Many islands of the eastern Indonesian Archipelago exhibit Late Cenozoic sequences of coral reef terraces. In SE Sulawesi, on the Tukang Besi and Buton archipelagos, we identified 23 islands bearing such sequences. Remote sensing imagery and field mapping combined to U/Th and ^{14}C dating enable to establish a chronologic framework of the reef terrace sequences from Wangi-Wangi, Buton as well as on the neighbouring, smaller islands of Ular, Siumpu and Kadatua. We identified the terraces from the last interglacial maximum (MIS 5e) at elevations lower than 20 m except on W Kadatua where it is raised at 34 ± 5 m. Such elevations yield low to moderate Upper Pleistocene uplift rates (<0.3 mm yr^{-1}). On SE Buton Island, a sequence culminates at 650 m and includes at least 40 undated strandlines. Next to this exceptional sequence, on the Sampolawa Peninsula, 18 strandlines culminate at 430 m. Dated samples at the base of this sequence (<40 m) yield mean Middle Pleistocene uplift rates of 0.14 ± 0.09 mm yr^{-1}. Extrapolation of these uplift rates compared to the geological setting suggests that the sequences of the Sampolawa Peninsula provide a record of sea-level high-stands for the last 3.8 ± 0.6 Ma. The sequences on SE Buton Island therefore constitute the best preserved long-lasting geomorphic record of Plio-Quaternary sea-level stands worldwide.

1. Introduction

Morphologic evidence of late Cenozoic sea-level changes mostly documents Middle and Upper Pleistocene times (Guilcher, 1969; Johnson and Libbey, 1997; Siddal et al., 2006; Bowen, 2010; Pedoja et al., 2011, 2014; Murray-Wallace and Woodroffe, 2014; Rovere et al., 2016). In fact, little is known about interglacials older than Marine Isotopic Stage 11 (MIS 11, 360–420 ka); their timing, duration and number of high-stands would have remained unknown if isotope records were not partly alleviating our lack of knowledge (Emiliani, 1955; Shackleton, 1987; Waelbroeck et al., 2002; Lisiecki and Raymo, 2005; Bintanja and Van de Wal, 2008; Zachos et al., 2008; Rohling et al., 2009). Sequences of coral reef terraces are widespread tropical indicators of ancient sea levels

(e.g., Lyell, 1830; Darwin, 1842; Daly, 1915, 1925; Berry et al., 1966; Broecker et al., 1968; Hibbert et al., 2016). Classic sites span the last 1 Ma (Sumba Island in Indonesia, Barbados Island) where only Upper and Middle Pleistocene terraces are dated (Pirazzoli et al., 1991, 1993; Radtke et al., 1988; Schellmann and Radtke, 2004). Finally, the famous Huon Peninsula in Papua New Guinea provides a detailed record of sea-level changes since MIS 5e (see concise site descriptions in Murray-Wallace and Woodroffe, 2014 and reference therein).

We describe a unique set of emerged sequences of marine and coral reef terraces from SE Sulawesi, which is a promising feature for understanding and reconstructing Lower Pleistocene and Upper Pliocene sea levels. Late Cenozoic slow to moderate uplift of SE Sulawesi led to the formation and preservation of spectacular sequences of strandlines (Satyana and Purwaningsih, 2011) that record the uplift of eastern Indonesia, an area that belongs to a larger region named the Maritime Continent (Molnar and Cronin, 2015). These sequences have been mentioned and briefly described (Verbeek, 1908; Fortuin et al., 1990; Tomascik, 1997; Satyana and Purwaningsih, 2011; Nugraha and Hall, 2018) but no chronologic framework has been proposed. Based on 13 U-series and 7 ^{14}C dates, we propose age constraints for the sequences located on the Tukang Besi and Buton archipelagos. We derive uplift rates on dated terraces, which we extrapolate to estimate the age of the sequences, and discuss these features within the geological framework of the area. Finally, we provide a general description of the late Cenozoic palaeogeographical evolution of the archipelagos and compare our results to other long-lasting sequences of emerged reef worldwide.

2. Settings

2.1. Regional geology

SE Sulawesi is surrounded by the Banda and Flores seas, where multiple islands cluster in the Buton and Tukang Besi archipelagos (Fig. 1). The Tukang Besi archipelago rests atop the Lucipara continental block, and is gradually colliding with the Kolodonale block that hosts the Buton Archipelago. Both blocks derive from the Bird's Head, a former fragment of the Australian plate now accreted to NE Papua (Hall, 2002), from which they detached during the separation of Gondwana (Pigram and Supandjono, 1985). During Oligocene and Miocene times, the Kolodonale block collided with Sulawesi, followed by the Lucipara Block (Hinschberger et al., 2005). Paleomagnetic data (Ali et al., 1996) suggest that collision took place during Pliocene times (~3 Ma) while more general plate reconstructions suggest an onset of collision at ~13 Ma (Hinschberger et al., 2005). This continental collision belongs to a larger convergent system that incorporates the oceanic Banda Basin, which is subducting underneath SE Sulawesi along the Tolo trough (Fig. 1B).

Pre-collisional rocks crop out in the centre of Buton Island, while the rest of the island is made of syn-collisional formations (Fortuin et al., 1990). The Tondo Fm. (11-7 Ma) is coarsening-upwards from silts to coarse bioclastic limestones. The Sampolakosa Fm. (7-3 Ma) is constituted at its base by chalk marls and at its top by reef limestone debris (Fortuin et al., 1990). The most recent Wapulaka Fm. developed as a veneer of reef limestone, formed by sequences of coral and marine terraces (Fortuin et al., 1990; Satyana and Purwaningsih, 2011; Nugraha and Hall, 2018). The Wapulaka

formation is proposed to have formed within the planktonic fora-minifera zones N21-N22/23 (Fortuin et al., 1990; Satyana and Purwaningsih, 2011). The zone N21 ranges from ~4.4 Ma to ~1 Ma (Hilgen et al., 2012) whereas zones N22/23 span the last 1 Ma (Pillans et al., 2012).

The Tukang Besi archipelago (Fig. 1B and C) exhibits a wide array of reef morphologies, from platform and table reefs to fringing and barrier reefs (Satyana and Purwaningsih, 2011). All the islands are either totally (e.g., Wangi-Wangi, Binongko) or partially (e.g. Kale-dupa) covered by sequences of coral and marine terraces and associated notches.

2.2. Coastal sequences of Indonesia

Sequences of marine and coral reef terraces are described on the eastern islands of the Indonesian Archipelago, north of the area where the Australian continent is colliding with the Banda Arc (Hantoro, 1992; Merritts et al.,1998; Major et al., 2013; Pedoja et al., 2014; Molnar and Cronin, 2015). Dated terraces are described within coastal sequences on the islands of Sumba (Hantoro, 1992; Pirazzoli et al., 1991, 1993), Alor (Hantoro et al., 1994), Sabu and Roté (Roosmawati and Harris, 2009), Atauro and Timor (Chappell and Veeh, 1978; Jouannic et al., 1988) and Kisar (Major et al., 2013) (Fig. 2). On Gunung Dirun (W Timor) a coastal sequence reaches

1293 m in elevation (Tomascik, 1997; Cabioch, 2011), which constitutes, to our knowledge, the highest elevation for such landform worldwide. In Eastern Indonesia, Upper Pleistocene (MIS 5e) strandlines are uplifted from 158 ± 7 m (Alor Island; Merritts et al., 1998; Hantoro et al., 1994) to 27.5 ± 2.5 m (Sabu Island, Hantoro, 1992) which yields apparent coastal uplift rates from 1.29 ± 0.08 mm yr^{-1} to 0.22 ± 0.02 mm yr^{-1} respectively (Fig. 2). North of the Australia - Banda Arc collision, uplift decreases (even if the elevation of MIS 5e is not well established at Luwuk, E Sulawesi) (Sumosusastro et al., 1989, Fig. 2). Following Verbeek (1908), Bird (2010) and Major et al. (2013), we identified at least 70 islands in Indonesia, where poorly studied coastal sequences could potentially complement our investigations. Most of them are located in the eastern part of the archipelago (Fig. 2).

In SE Sulawesi, Verbeek (1908) first sketched the staircase coastal landscapes of Wangi-Wangi Island and of the Sampolawa Peninsula (SE Buton). Kuenen (1933) analyzed the bathymetry of the Tukang Besi archipelago. Tjia et al. (1974) mentioned a sequence of 14 terraces on Tomea Island (Tukang Besi Archipelago) and focused on the lowest terrace (see below). Fortuin et al. (1990) described 14 terraces on the Sampolawa Peninsula (SE Buton). In SW Buton, a coral sample collected from a terrace at 92 m in elevation yielded a U/Th age of 182 ± 27 ka (Fortuin et al., 1990). Finally, Satyana and Purwaningsih (2011) provided a distribution of
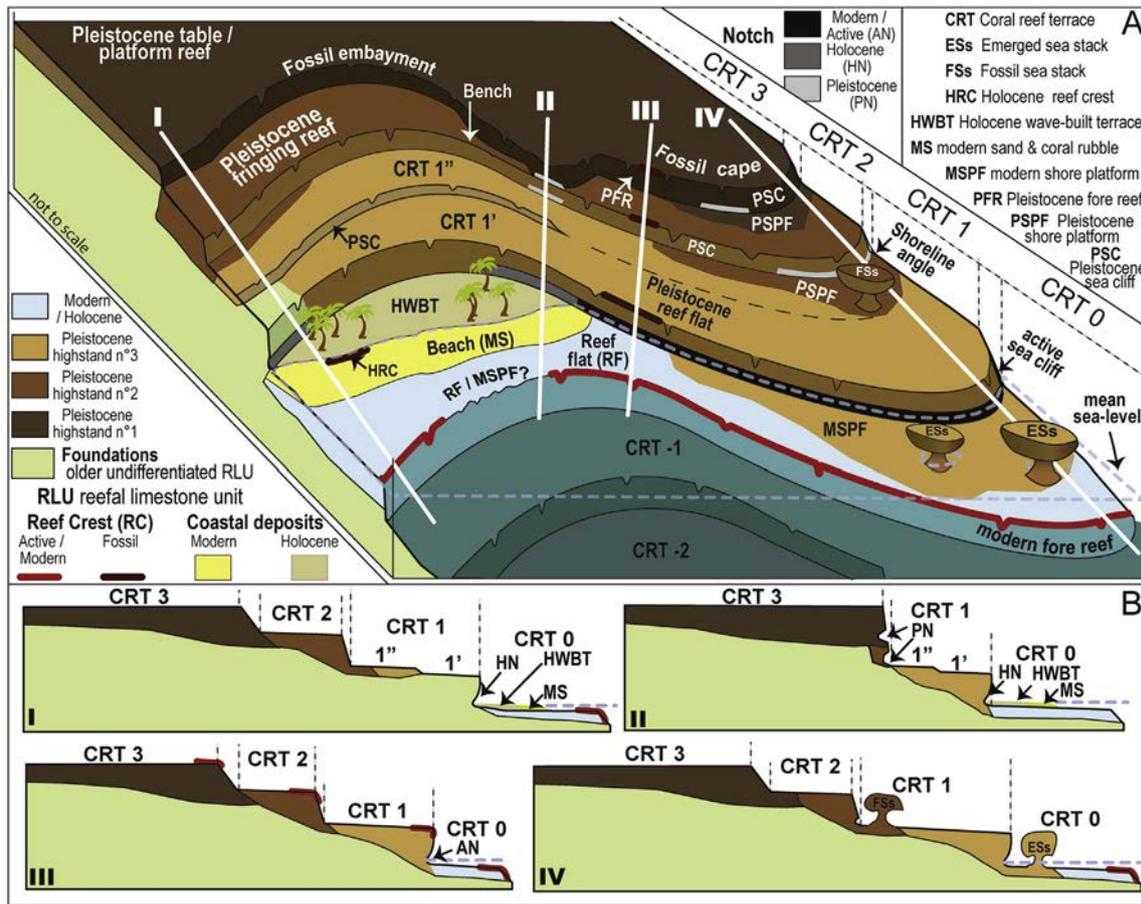

Fig. 3. Coastal erosion processes within the formation of coral reef terraces. A) Three dimensional schematic view of a sequence of coral reef terraces (CRT) from a bay to a cape B) Transects across the coral reef terraces. Terraces, emerged or submerged, are defined as sub-planar, shallowly seaward–dipping surfaces between marine cliffs. Marine cliffs are 2–20 m high, generally strike parallel to the coast, and define a fossil cape and a fossil embayment. All the CRT are fossil fringing reefs except CRT 3 which is a fossil table or a platform reef. The number and geometries of successive CRT vary alongshore: for instance, CRT 2 is replaced by a notch on transect II. Basically, erosion at sea level truncates an ancient reef limestone unit, what result in the formation of a terrace including various reef limestone units (RLU). Because of global isostatic adjustment, depositional, constructional and erosional landforms of the Holocene-modern shoreline are diachronic by a few thousand years: CRT 0 includes modern coral on the reef crest, Holocene coral on the reef flat and on the upper tidal area. Locally the Holocene reef is overlaid by younger Holocene deposits from the wave-built terrace (HWBT).

the uplifted coasts of Sulawesi that includes brief morphological descriptions of Wangi-Wangi and SE Buton.

Regional variability of sea-level changes since the Last Glacial Maximum (~20 ka BP) results from the combination of glacio-isostatic adjustment (GIA), tectonics and other local processes (Shennan and Horton, 2002; Milne et al., 2005; Lambeck et al., 2012, 2014). Variable regional timings of the mid-Holocene highstand in Tropical Pacific sea level are reflected by frequent discrepancies in calibrated radiocarbon ages for emergent mid-Holocene fossil reefs (Dickinson, 2001; Woodroffe and Horton, 2005), that can readily be attributed to GIA (Mitrovica and Milne, 2003). On Tomea (Tukang Besi Archipelago, Fig. 1B), Tjia et al. (1972, 1974) radiocarbon dated a mollusc shell from a terrace whose shoreline now stands at 10 m. The shells, that yielded an age of 1120 ± 90 yr, were collected in crevices of the coral reef terrace. The authors correlated the wide, low-lying terrace to the Holocene and calculated an uplift rate of 8.4 mm yr^{-1} (Tjia et al., 1972). At various sites from the Spermonde archipelago (Fig. 1A), off the Southwest Sulawesi Peninsula, 320 km westward of Buton, the amplitude of the GIA was more recently re-evaluated to be less than +1 m instead of the +5 m previously estimated (see Mann et al., 2016 and reference therein).

## 3. Emerged sequences of tropical strandlines and estimates of tectonics uplift

Marine and coral reef terraces, emerged in sequences, are stacked fingerprints of the course of sea-level changes on rising coasts (e.g., Lajoie, 1986). These fingerprints are associated to interglacial sea-level high-stands (associated to odd-numbered MIS), and well recognized throughout the Quaternary (Murray-Wallace and Woodroffe, 2014). When a terrace is dated, its shoreline angle provides a good approximation to the location and elevation of a former strandline and, hence, a marker for relative sea level (Lajoie, 1986; Speed and Cheng, 2004). Sometimes, only the altitude of the fossil reef or the fossil shore platform can be determined and be used as a sea-level indicator (as in Mangaia Island, Cook islands, Ward et al., 1971).

3.1. Marine terraces and coral reef terrace revisited

Most geomorphic definitions formally distinguish marine terraces from coral reef terraces (van de Plassche, 1986; Pirazzoli, 1994; Pedoja et al., 2011; Murray-Wallace and Woodroffe, 2014). Marine terraces result from the effects of marine erosion (also called wave-cut terraces or fossil shore platforms) and accumulation of sediments at shallow depths (wave-built terraces) (Pirazzoli, 2005a; b). The shoreline angle of a terrace corresponds to the intersection of the platform with the sea cliff (Fig. 3; Lajoie, 1986). Notches are horizontal incisions in cliffs (Fig. 3) with widths and excavation depths that reach up to a few metres. Notch types reflect a continuum from wave notches that form under quiet conditions at sea level to surf notches that form as much as 2 m above sea level (Pirazzoli, 1994). In inter-tropical regions, coral reefs are present and fossilized as coral reef terraces (Chappell, 1974) sometimes also called emerged reef, reef terraces (Hopley, 2005; Cabioch, 2011), or elevated reefs (Darwin, 1842). A coral reef terrace (CRT on Fig. 3) results from the combination of bioconstruction, erosion at sea level and subsequent accumulation of the eroded sediments (Pirazzoli, 2005a; b; Cabioch, 2011). It corresponds to a reef flat, or a reef platform. i.e., a stony expanse of reef rock with a flat surface (Pirazzoli, 2005a; b). Most generally, this surface is limited seaward by a frontal crest and a fore reef, and landward by a break in slope and a shoreline angle, sometimes underlined by a notch (Cabioch, 2011), and a fossil shore platform (i.e. a marine terrace, this study).

Besides some exceptions (Bloom et al., 1974; Stoddart and Spencer, 1987; Pirazzoli et al., 1993; Blanchon and Eisenhauer, 2000; Speed and Cheng, 2004; Montaggioni and Braithwaite, 2009; Cabioch, 2011), coastal erosion which results in the formation of rocky-shore platforms, notches, and visors (the modern equivalent of a marine terrace), during the formation of coral reef terraces, is largely underestimated. *De facto*, since the seminal works on the Huon Peninsula (Papua New Guinea; Bloom et al., 1974; Chappell, 1974) many studies simply postulate that a coral reef terrace corresponds to a single reef limestone unit (RLU on Fig. 3). It is regarded as a single, most generally fringing reef, built during a transgression until the eustatic peak associated to a sea-level high-stand, and ignores the erosive counterpart. Such postulate allows to use the reef crest of a fossil fringing reef as a tectonic benchmark (e.g. Lecolle et al., 1990) compared to the shoreline angle of the terrace as used in this study.

The various interplays between construction, deposition and erosion that we observed alongshore many islands of the Indonesian archipelago (SE and SW Sulawesi, Spermonde, Belitung, Sumba, Bali, Lembogan, Lombok …) are synthesized on Fig. 3. Reef
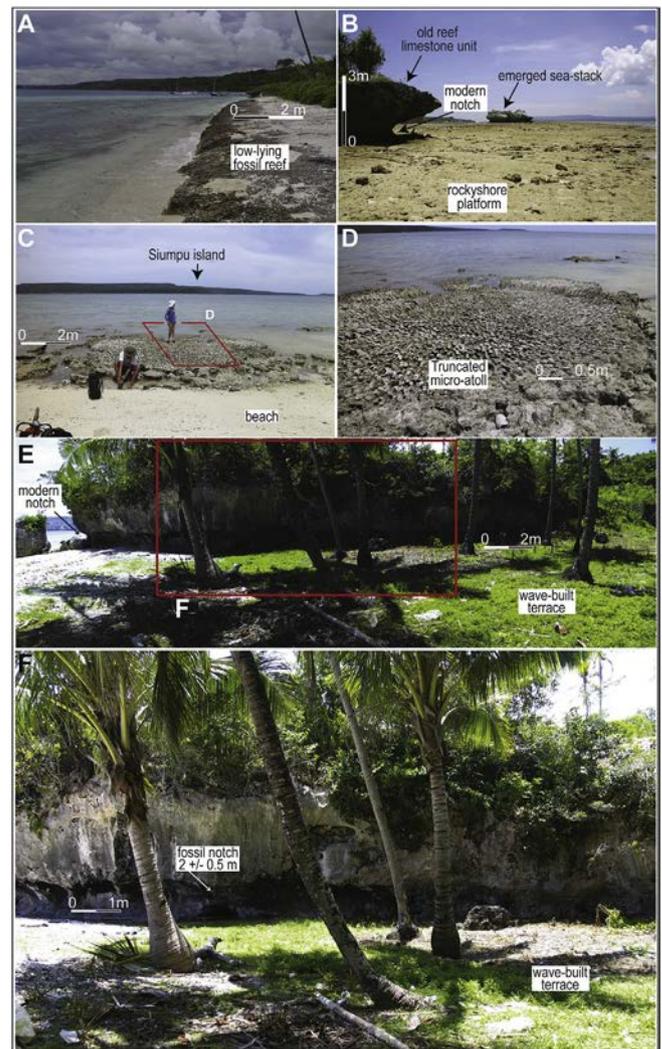

Fig. 4. The Holocene coastal record. **A)** Holocene reef, W Siumpu. **B)** Shore platform, notch and sea-stack, W Kadatua. Errors are 2σ

crests and reef flats are not always present alongshore. Some stretches are carved into notches and shore platforms, others include beaches, estuaries, mangroves … When present, the fossil record exhibits the same alongshore variations of erosional landforms, deposits and construction whose gradual demise becomes more obvious as coastal landforms age (section 4.1).

During a given sea-level high-stand, the reef limestone unit is discontinuous alongshore. Moreover, such units are prone to erosion after their deposition, specifically at sea level, and many tropical rocky shores are carved into more ancient reef limestone. In SE Sulawesi, the surface of coral reef terraces are eroded, as highlighted by the truncation of underlying strata (Fig. 4) and the occurrence of fossil sea stacks, as described elsewhere (Speed and Cheng, 2004). In other words, within a sequence of coral reef terraces, the subsurface distribution and thickness of the various reef limestone units are not accessible directly on field. This lack of knowledge has strong implications for age determinations: a terrace can be associated to more than one reefal limestone unit thus host samples of multiple ages (see Fig. 3 for more details).

3.2. Mapping method

We mapped the studied coastal sequences based on field observations complemented by satellite imagery (Landsat, Spot, SRTM). We measured the elevations of fossil shoreline angles with barometric altimeters and/or differential GPS (dGPS, Trimble XT). Barometric altimeters were used mostly for the low-lying terraces that we surveyed repeatedly (3−5 measurements). We tied the elevations to modern sea level, as defined by the retreat point of the modern notch or by the last high-tide mark. Beside instrumental errors, we assigned a margin of error to all field measurements. The natural rugosity of the landforms is the main source of error; far beyond instrumental errors. The roughness of the landforms increases with elevation and age. For low standing landforms, the margin of error is set to ± 2 m whereas for upper strandlines it reaches ± 10 m because of increased erosion and karstification with altitude.

3.3. U/Th and ^{14}C dating

Fossil coral colonies (Merulinidae fm.; Favites sp., Dipsastraea sp., Platygyra sp.), found in life-position on the terrace of the studied sequences were sampled with a portable core drill device. Thin sections of the selected corals were first inspected with a microscope to discard recrystallized portions. Thirteen selected samples were crushed into chips of 0.5−1 cm and mechanically cleaned. The coral samples were rinsed in milliQ water multiple times and leached in 0.1 N bi-distilled HCL for 15−20 min in an ultrasonic bath. The cleaned samples were crushed into powder and X-rayed at the ISTerre facility (Grenoble, France) to quantify the extent of calcite recrystallization if any. Sample powders were weighed

500 mg and spiked with a mixture of ^{229}Th, ^{233}U and ^{236}U prior to dissolution in 6N HCl at 100 °C. The fractions of Th and U were separated using the simplified UTEVA column chemistry method from Douville et al. (2010). The required ^{238}U, ^{232}Th concentrations and U-Th isotopic compositions for U-series disequilibrium dating were measured on the ICP-MS quadrupole mass spectrometer Thermo Fisher Scientific X series II at the Laboratory for Climate and Environment Sciences (LSCE, Gif-sur-Yvette, France) as described in Douville et al. (2010). Table 1 presents the analytical results. All coral samples display ^{238}U concentrations between 2 and 2.5 ppm. The low ^{232}Th contents together with high (^{230}Th/^{232}Th) activities ratios argue for the absence of significant detrital contamination. Most of the samples display initial δ^{234}U values that agree within errors with modern ocean water values of δ^{234}U $= 148 \pm 10$ (Chen et al., 1986; Cheng et al., 2000), which indicates isotopic Th-U evolution in a closed system.

Seven ^{14}C dating of Tridacnidae shells and corals from the lowermost terraces (Table 2) were performed at the Laboratoire de Mesure du Carbone 14 (LMC14). After removing any surface contamination by sand blasting the outer surface of shells and corals, the samples were cleaned with distilled water in an ultrasonic bath. The carbon isotopes were measured with the Artemis AMS facility of the LMC14. This facility is based on a 9SDH-2 Pelletron tandem from National Electrostatic Corporation. The procedure is extensively described in Dumoulin et al. (2017).

3.4. Sea level curves and uplift rates

Based on U/Th and ^{14}C dating, we propose the morphostratigraphy and ranges of uplift rates deduced from the elevation of the marine terraces allocated to upper and middle Pleistocene interglacials (MIS 5e and MIS 9). Eustasy-corrected uplift rates are given by dividing the difference between the present elevation of the shoreline angle and the eustatic sea level at its formation time by the age of the terrace (Lajoie, 1986). We compute, for reference, apparent uplift rates (Table 3) that neglect any a priori eustatic correction (as in Pedoja et al., 2011, 2014; Yildirim et al., 2013; Authemayou et al., 2016).

Several sea-level curves have been derived from the oxygen isotopic records (Shackleton, 1987; Waelbroeck et al., 2002; Lisiecki and Raymo, 2005; Bintanja and Van de Wal, 2008; Zachos et al., 2008; Rohling et al., 2009), but also from -or combined to-the geomorphologic record (Siddal et al., 2006; Murray-Wallace and Woodroffe, 2014). These sea-level curves often present discrepancies in the ages and magnitudes of the MIS (Table 3; see also Caputo, 2007; Murray-Wallace and Woodroffe, 2014), but there is a relative consensus on the succession of the most recent highstands. The most common high-stand in the geomorphological record is the last interglacial period, MIS 5 (Stirling et al., 1998; Pedoja et al., 2011; Murray-Wallace and Woodroffe, 2014), that includes three relative high-stands, MIS 5a (85 ± 5 ka), MIS 5c

[a] Waelbroeck et al., 2002 built a composite relative sea level curve, over the last four climatic cycles, from long benthic isotopic records retrieved at one North Atlantic and one Equatorial Pacific site.

[b] Bintanja and Van der Wal, (2008) used an ice-sheet model and a simple ocean-temperature model to extract three-million-year mutually consistent records of surface air temperature, ice volume and sea level from marine benthic oxygen isotopes.

[c] Grant et al. (2014) proposed a chronology derived from a U/Th-dated speleothem d 18 0 record, for a continuous, high-resolution record of Red Sea relative sea level over five complete glacial cycles (500 kyr).

[d] Shakun et al., (2015) through a global compilation of 49 paired sea surface temperature-planktonic d 18 0 records extracted the mean d 18 0 of surface ocean seawater and eustatic curve over the past 800 kyr.

[e] Spratt and Lisiecki (2016) performed principal component analysis (PCA) on seven records from 0 to 430 ka and five records from 0 to 798 ka.

(105 ± 5 ka) and MIS 5e (128 ka to 116 ka). MIS 7 ranges from 190 to 245 ka (Thompson and Goldstein, 2005), and includes sub-stages 7a (190−200 ka), 7c (206−217 ka) and 7e (231−248 ka) (Dutton et al., 2009). In Henderson Island, South Pacific, two sea-level high-stands have been observed during MIS 9: sub-stages 9a and 9c extending from 306 ± 3 ka to 334 ± 4 ka respectively (324.5 ± 18.5 ka) (Stirling et al., 2001). MIS 11 lasted from 420 ka to 360 ka (Murray Wallace and Woodroffe, 2014). Earlier interglacial periods are MIS 13 (480−530 ka), MIS 15 (560−620 ka) and MIS 17 (650−720 ka) (Thompson et al., 2003; Andersen et al., 2008; Murray-Wallace and Woodroffe, 2014).

In order to account for the variability of sea-level curves, we analyzed the sequences of SE Sulawesi in the framework of the latest compilation of geomorphic indicators (Murray-Wallace and Woodroffe, 2014) but also with five eustatic curves (Table 3, Waelbroeck et al., 2002; Bintanja and Van de Wal, 2008; Grant et al., 2014; Shakun et al., 2015; Spratt and Lisiecki, 2016). Murray-Wallace and Woodroffe (2014) consider that MIS 5e, MIS 7, MIS 9, and MIS 11 high-stands were respectively at 6 ± 4 m, −8 ± 12 m, 3 ± 2 m, and 9.5 ± 3.5 m with respect to present-day sea level (Table 3). The five sea-level curves were selected to encompass five different reconstruction methods, cover the time-range of interest (at least up to 420 ka) and have quantified uncertainties (see Table 3 for more details) (Waelbroeck et al., 2002; Bintanja and Van de Wal, 2008; Grant et al., 2014; Shakun et al., 2015; Spratt and Lisiecki, 2016). These different estimates of past sea levels translate into different estimates of uplift rates (Table 3) that are discussed section 5.2.

4. The coastal sequences of SE Sulawesi

Sequences of strandlines are present on at least 23 islands off SE Sulawesi, with the exception of Kabaena (Figs. 1C and 2). They either cover entire islands (Wangi-Wangi, Kadatua, Muna) or coastal stretches (Buton, Kaledupa or Wowoni) (Fig. 1C). The sequences often correspond to elevated reef platforms and table reefs bordered by staircase marine and coral reef terraces, which constitute elevated limestone islands (as defined in Schwartz, 2005).

4.1. Holocene record

At coastal sites of SE Sulawesi, we observed, at elevations from ~0.5 to 5 m, an array of landforms and deposits, including notches, fossil coral reefs and coastal deposits ("wave-built deposits"). Low landforms are better preserved than their higher, older counterparts (Fig. 4A-D). Low-lying terraces are a few metres or a few tens of metres wide when higher terraces are reaching hundreds of metres wide. Coastal deposits such as coral rubble (HWBT in Fig. 3) are absent from high terraces that exhibit only eroded coral reef limestone. Finally, low-lying landforms form a morphological continuum toward the modern coast. For example, at the eastern and western tips of the Bahari embayment, the modern notch (the one reached by high tides) is morphologically continuous with a fossil notch, (buried with sand) (Fig. 4E and F) that reaches an elevation of 2 ± 0.5 m to the west of the bay (see photogrammetric model at https://goo.gl/Ds4vWX).

To the SW of Buton Island (Figs. 5 and 6), at Lakeba, a low-lying sedimentary terrace, up to 40 m wide, backs up the modern beach. Sedimentary deposits are composed of poorly consolidated, shelly rudstones including coral rubbles. The terrace is bounded inland by a ~3 m high cliff, sometimes associated to a 1.5−2 m high notch carved in an older reef limestone. Within the intertidal zone, below the rudstones, we observed in situ fossil corals that we interpreted as remnants of an emergent low-lying fossil reef which distal part is now located between spring and neap high tide marks (Fig. 6B). We sampled coral samples for U/Th and ^{14}C dating. A fossil coral taken in the fossil reef exposed on the upper part of the sandy tidal flat of Lakeba, less than 20 cm below high-tide mark (Table 1, GSL-2012-47) was U/Th dated. Tridacnidae and coral samples from the coastal deposits (Lakeba 1, 2A and B) (Table 2) were ^{14}C dated. GSL-2012-47 yielded a U/Th age of 7.2 ± 0.2 ka whereas ^{14}C-dated samples Lakeba 1, 2A and 2B yielded ages of 3100 ± 30 yr, 2935 ± 30 yr, 2930 ± 30 yr BP, respectively (Table 2). We relate the fossil, emergent, reef and the posterior deposits of the wave built terrace to Holocene GIA within the area.

Offshore SW Buton Island (Fig. 5), Ular is a small (1.5 × 0.5 km), inhabited island. It is surrounded by a fringing reef that is backed-up by a rocky-shore platform and associated notch along some part

of the island coastal stretch (Fig. 6C and D). The island includes two terraces and a reef platform raised at ~50 m (Fig. 6C and D). The lowermost terrace, to the east of the island, is mainly composed of wave-built coral rubbles up to 5 ± 1 m. This terrace is backed by a fossil notch. To the north of the island, there is a continuum between the fossil to the modern notch (see section 4.1). On the modern rocky shore platform, we sampled fossil corals and Tridacnidae for U/Th (GSL 2014-13) or ^{14}C dating (GSL 2016-44, GSL 2016-50, GSL 2016-53, GSL 2016-59; Table 2). GSL 2014-13 yielded a

U/Th age of 184.7 ± 8.9 ka. GSL 2016-44 (Tridacnidae) yielded a ^{14}C age of 0.745 ± 0.030 ka while GSL 2016 50, 53 and 59 yielded ages that we interpret as minimum because at the limit of the method. Finally, we allocated the eroded reef unit and surrounding terrace to MIS 7 (Table 1). The carving of the platform is, of course, posterior, ranging from Holocene to modern time. Locally, the platform includes Tridacnidae shells or micro atolls developed on older reef units.

Our dating confirms the global observation (van de Plassche,
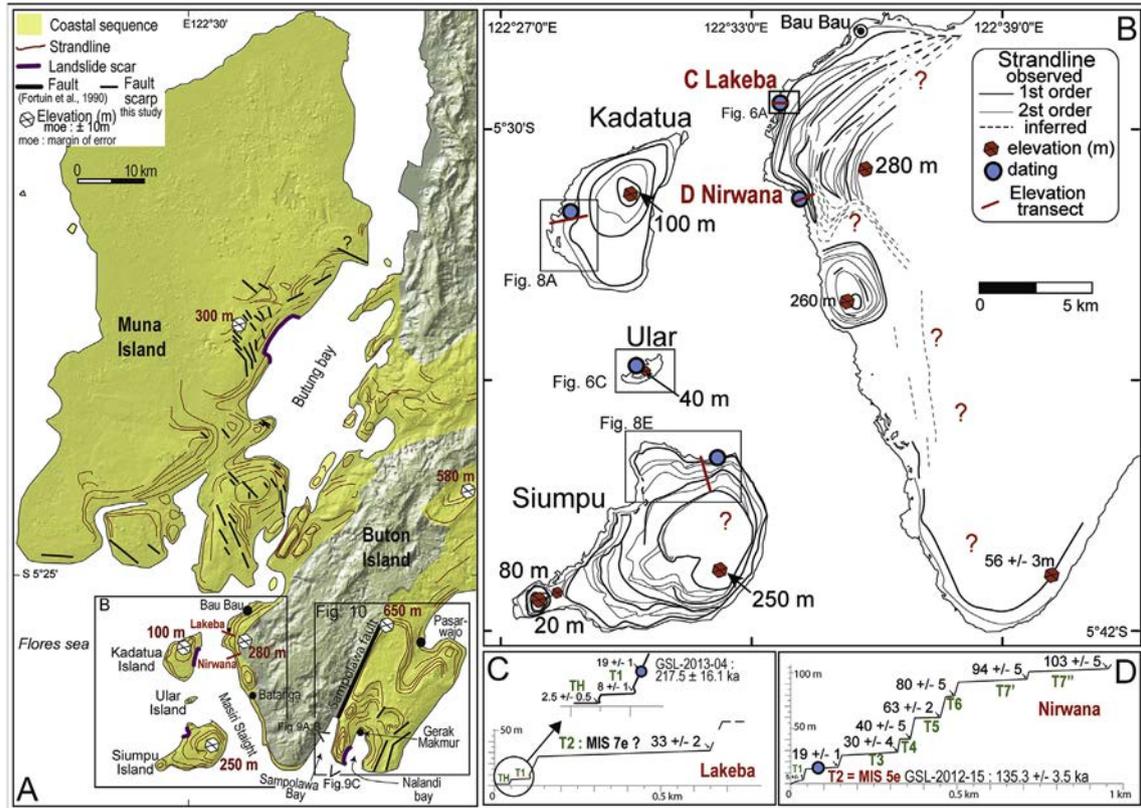

Fig. 5. A) Sequences of marine and coral reef terraces, active faults and landslides on Muna and S Buton islands **B)** Sequences of coral reef terraces on SW Buton, Kadatua, Ular and Siumpu islands. For mapping facilities, we distinguish 1st order and 2nd order strandlines. The code is based on the observation of the terrace on satellite images and does not always reflect the field (cloud, for example). **C)** Simplified transect and dating at Lakeba, SW Buton **D)** Transect and dating at Nirwana, SW Buton. On both transect, the numbers correspond to the elevations (in metres) above mean sea level.

Fig. 6. Dated Holocene coastal landforms **A)** Landsat image of Lakeba area, SW Buton. **B)** Sampled outcrop at Lakeba; **C)** Landsat image of Ular Island, off SW Buton. **D)** Interpreted aerial picture of the northern shore of Ular Island. **CRT**: coral reef terrace, **RPF**: reef platform, **FS**: fault scarp, **FR**: fringing reef, **SP**: rocky shore platform, **WBT**: wave-built terrace. The numbers correspond to the elevations (in metres) above the mean sea level.

1986; Pirazzoli, 1994; Pedoja et al., 2014; Murray-Wallace and Woodroffe, 2014) that the geomorphic characteristics of the low landforms (limited widths, reduced karstification, occurrence of soft sediments) are indicative of their young age (Holocene). At each studied site in SE Sulawesi, we therefore postulate that low-lying landforms (TH < 5 m) relate to the mid-Holocene high-stand (~9−3 ka), while the rest of the sequence is Pleistocene or older in age.

4.2. Wangi-Wangi

Wangi-Wangi, to the North of the Tukang Besi Archipelago (Figs. 1C and 7), has a ~50-km-long coastal stretch for a total area of ~200 km^2 (Fig. 7B). On the island, the distribution of coral reef terraces (Fig. 7B, C, D) reveals the uplift and coalescence of two main reef platforms. The largest reef platform, that we named Tindoi (Fig. 7B) is 12-km-long, up to 3.5-km-wide and trends NW-SE. In the central part of the platform, there is a reduced reefal limestone hill at 240 ± 10 m. The second fossil reef platform, that we named Numana (Fig. 7B), is smaller, 4-km long and up to 3-km-wide, more circular in shape (Fig. 7B) and reaches a maximum elevation of 60 ± 10 m. The sequence around the Tindoi reef plat-form (180 ± 20 m) includes at least five terraces with some distinct shoreline angles at 68 ± 5 m and 98 ± 7 m. The southern fossil reef platform at 60 ± 10 m is surrounded by, at least, two terraces (Fig. 7B).

On the NE shore of Wangi-Wangi, the Patuno Resort is built on a narrow wave-built terrace associated to a notch (1.5 ± 0.5 m) that we correlate to the Holocene (see 4.2, Fig. 7B and E). The ~10 m high fossil sea cliff exhibits two other notches at elevations of 4 ± 1 m and 7 ± 2 m. Terrace T1 is ~800 m wide and its shoreline angle is raised at 17 ± 2 m (Fig. 7C). We sampled corals in T1 limestone (Fig. 7C) at the summit ($+4$ m) of the double notch off Patuno resort (GSL 2013-50), and at the distal edge (~11 m) of T1 terrace (GSL 2013-54). Samples GSL 2013-50 and GSL 2013-54 yielded U/Th ages of 133 ± 4 ka and 131 ± 4 ka respectively (Table 1). We allocate the limestone unit and terrace T1 to the last interglacial maximum (MIS 5e).

4.3. SW Buton and islands

The city of Bau Bau (SW Buton) is built on a sequence of coral reef terraces (Fig. 5A). This sequence forms a fossil cape conform to its modern counterpart (Fig. 5B) and when observed from the sea, appears as a gentle anticline whose maximum elevation reaches ~280 m westward of Lakeba (Fig. 5A). In Bau Bau area, we identified at least 11 successive terraces up to ~180 m. Samples were collected from Lakeba and Nirwana areas, to the South of the city (Fig. 5B).

At Lakeba, we focused on the Holocene strandline (section 4.1, Fig. 6 A, B). Above the sedimentary TH terrace, there is a reduced T1 terrace (Fig. 6A. To the North of Lakeba, T1 terrace width is ~4−10 m and its shoreline is raised at 7 ± 2 m. In the centre of the bay, T1 shoreline is associated to a notch at 8 ± 1 m (Fig. 6A). Above T1, there is a wide coral reef terrace, T2, whose shoreline is present at
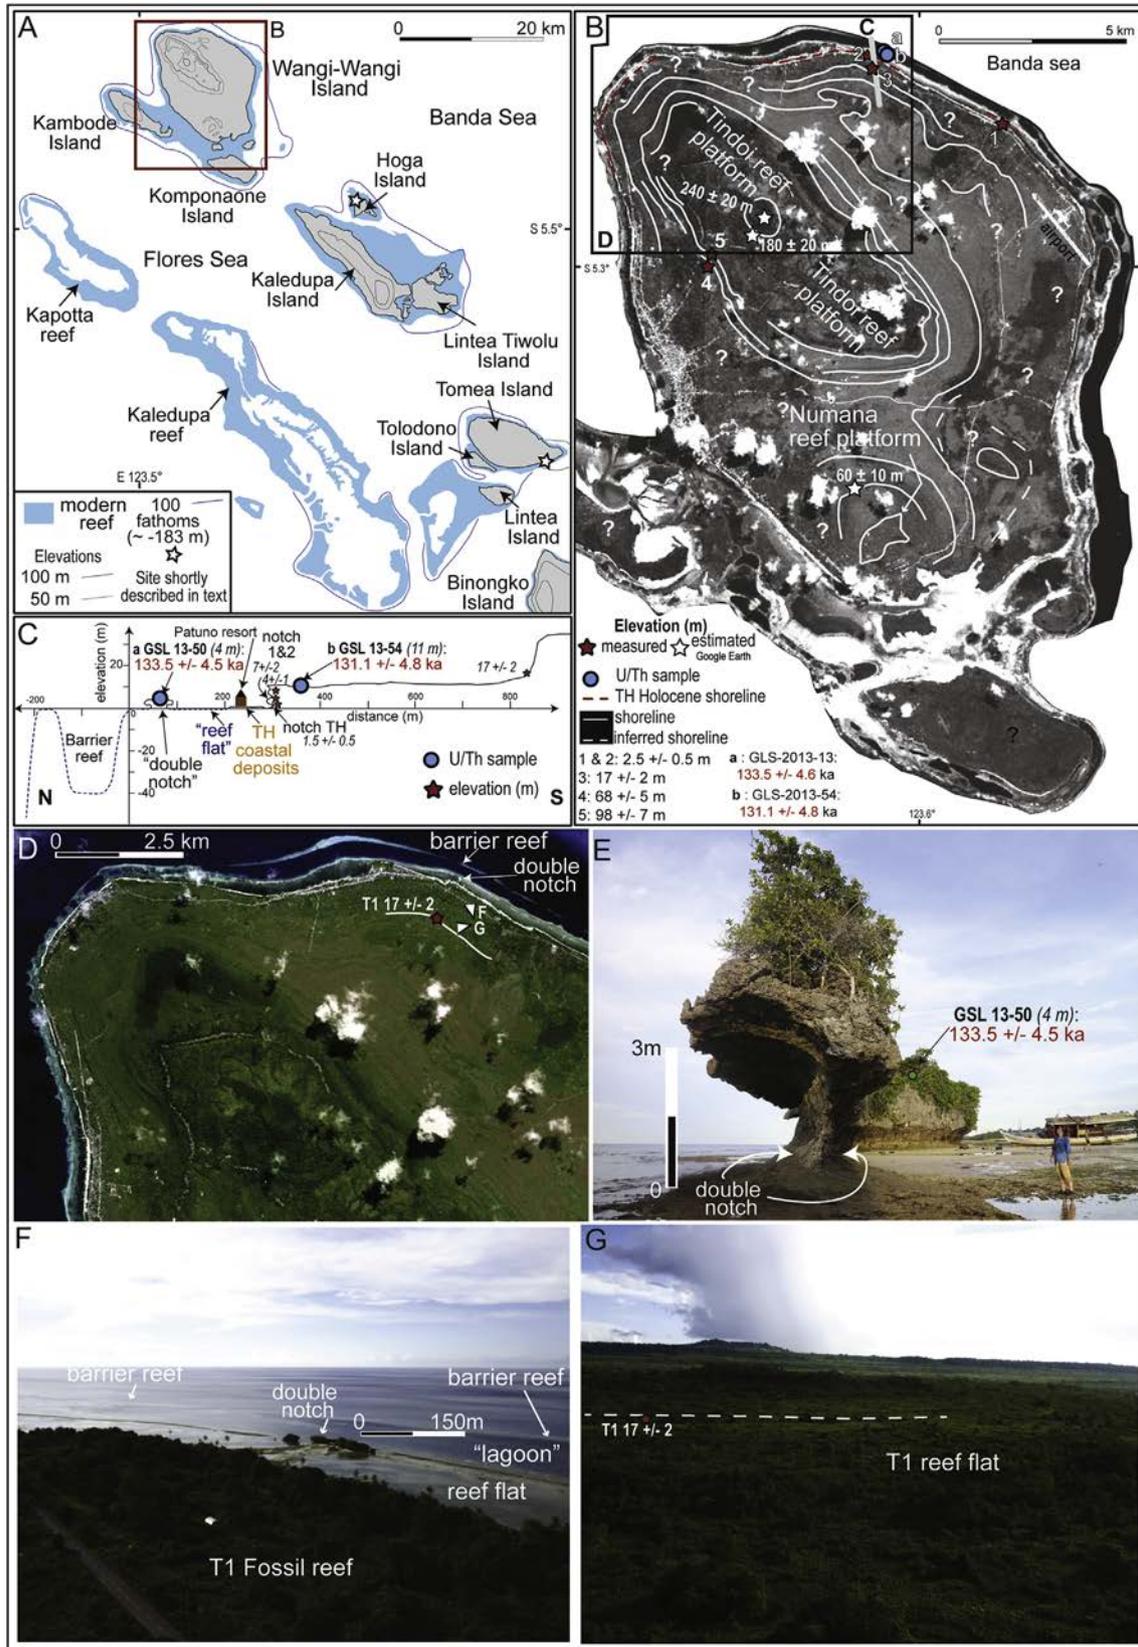

Fig. 7. A) Sequences of marine and coral reef terraces on the north Tukang Besi archipelago (location on Fig. 1). **B)** Strandlines on Wangi-Wangi Island **C)** Elevation transect and dating (location on panel B, grey line) **D)** Landsat image of N Wangi-Wangi Island showing the coral reef and marine terraces distribution and the upper Tindoi platform (see text for more details). **E)** The double notch at Patuno resort, NE Wangi Wangi, where we sampled GSL 13−50. **F)** and **G)** Interpreted aerial pictures of the modern shoreline and the T1 coral reef terrace next to Patuno resort.

33 ± 2 m where the city airport stands (Fig. 6A). To the North, T1 is discordant on Sampolakosa Fm. We extracted coral samples in the fossil sea cliff associated to CRT 1 (sample GSL 2013 -04) at an elevation of $18-20$ m. Sample GSL 2013-04 yielded a U/Th age of 217.5 ± 16.1 ka (Table 1). We tentatively allocated the upper T2 terrace to MIS 7.

To the south of Nirwana bay, we measured the elevation of eight successive strandlines up to 103 ± 5 m (Fig. 5D). We sampled GSL 2012 -15 to the north of the bay at the elevation of T2 (~20 m), but in an area where the terrace morphology is not obvious due to faulting and urban development. GSL 2012 -15 yielded a U/Th age of 135.3 ± 3.5 ka, which leads us to correlate T2 to MIS 5e high-stand (Table 1).

Kadatua Island is 8 km long and 4.5 km wide. It reaches elevations of ~100 ± 10 m (Fig. 5B). On its western side, from the sea to one of the widest terraces of the sequence (T4 on Fig. 8A), we identified 3 successive strandlines (Fig. 8A, B, C, D), T1, T2 and T3 up to 35 ± 4 m. T2 is a compound terrace (T2′ and T2″ on Fig. 8C). We sampled corals from T2″ (GSL 2012-13 and duplicate) and T3 (GSL 2013-69 and GSL 2013-70) (Fig. 8B and C). Corals samples drilled in T2″ yielded U/Th ages of 189.3 ± 2.8 ka (GSL 2012-13) and 194.3 ± 10.9 ka (GSL 2012-13 and duplicate) (Table 1, Fig. 8C). Samples drilled in T3 yielded U/Th ages of 127.5 ± 2.8 ka (GSL 2013-69) and 128.17 ± 2.7 ka (GSL 2013-70) (Table 1, Fig. 8C). The straightforward morpho-stratigraphic interpretation would consist in allocating T2″ to MIS 7a and the T3 terrace to MIS 5e. We discard this hypothesis because coastal erosion truncates underlying strata. Consequently, we allocate T3 to MIS 5e high-stand and suggest that carving of T2″ occurred later (MIS 5c, 5a?), into a reef limestone unit

related to MIS 7.

Siumpu Island is 10 km long and 5 km wide (Fig. 5A and B). As Wangi-Wangi, it is composed of two coalescent uplifted reef platforms bordered by extensive sequences of coral reef terraces (Fig. 5B). The largest reef platform, in the NE of Siumpu, is raised at ~250 m whereas the smallest one is raised at ~80 m (Fig. 5B). In NE Siumpu, the sequence includes a minimum of 15 successive strandlines. We studied its lower part and recognized nine successive terraces, up to ~160 m (Fig. 8E, F, G). The shoreline angle of T3 was measured at 54 ± 1 m (Fig. 8G). GSL 2012-33 was sampled in the limestone constituting the distal edge of the terrace (Fig. 8F and G) and yielded a U/Th age of 245.6 ± 13.1 that we correlate to MIS 7e (Table 1).

4.4. SE Buton

West of the Sampolawa fault (Fortuin et al., 1990), SE Buton Island consists in a ~12×7 km, fossil reef platform, heavily karstified and bordered by extensive sequences of marine and coral reef terraces to the north and south (Figs. 9–12). On its SE side, the fossil reef platform does not display any terrace (Fig. 10A). In the Gulf of Pasarwajo, we identified a minimum of 40 successive terraces on satellite images (Fig. 10B) reaching a maximum elevation of 650 ± 10 m to the NE (Fig. 10A and B). Field data and SRTM satellite images and DEM (Fig. 10C-F) reveal that the terraces are clearly tilted, warped and faulted. Their large-scale deformation outlines the underlying anticline (Fig. 10A, E). In the Gerak Makmur area, at least 30 successive terraces up to 550 ± 10 m in elevation circumscribe two embayments that coalesced to form the modern Nalandi
Fig. 8. bay (Fig. 10A). At Laboke point, NE-SW trending faults delimit the distribution of the staircase sequence that reach ~180 m and in-cludes at least 13 terraces. At all sites, within the reef limestone of the low standing terraces, the lack of pristine coral samples pre-cluded U/Th dating.

The 6 km-long and 2-3 km-wide Sampolawa Peninsula is delimited by the Nalandi Bay (E) and the Sampolawa Fault (W) (Fig. 10A). It exhibits a notable sequence of fossil reefs (see

Figures in Verbeek, 1908; Fortuin et al., 1990; Pedoja et al., 2011), that culminates at 430 ± 10 m and includes a minimum of 18 suc-cessive strandlines (terraces, notches). On its SE side, the peninsula is indented by large landslides (Figs. 9—11). Between Bahari and the south of Tira (Fig. 11A and B), the shoreline angles of the terraces and the notches are horizontal and laterally continuous over ~2 km (Fig. 11A and B), even if they sometimes display lateral geomorphic changes from fringing reefs to notches, for example. South of Tira
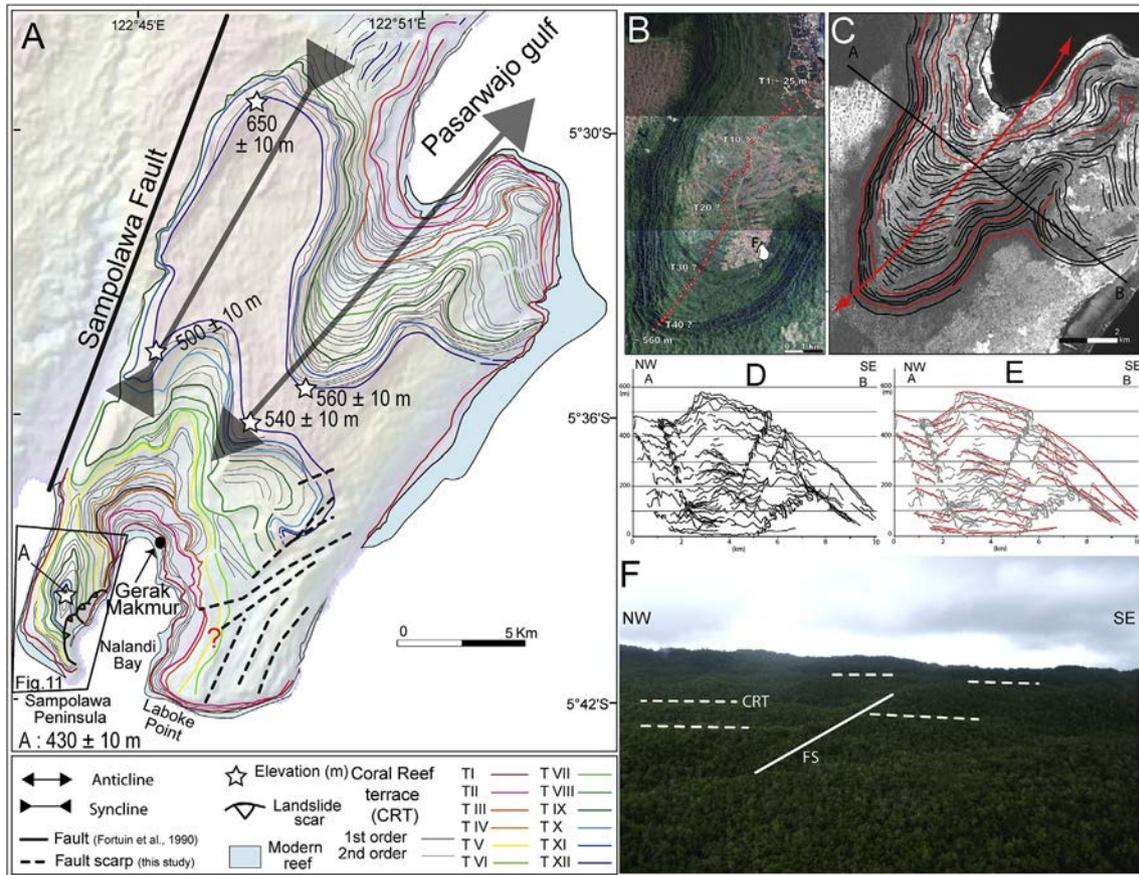

Fig. 10. A) Sequence of coral reef and marine terraces and tectonic structures on SE Buton Island. For mapping facilities, we colour-coded some of the successive terraces and distinguished 1st order and 2nd order strandlines. The code and distinction are based on the observation of the successive terraces on satellite images and does not always reflect the field (faulting for example). **B)** Landsat image showing the sequence of 40 coral reef and marine terraces in the Pasarwajo fossil gulf. **C)** Interpreted SRTM DEM of the Pasarwajo fossil gulf **D)** Projected topographic profiles of the coral reef and marine terraces along the AB cross-section from the SRTM DEM. **E)** Extrapolation of the deformation path of the successive shoreline angles along the AB cross-section. **F)** The sequence of coral reef and marine terraces in the fossil gulf of Pasarwajo. village, a system of NE trending vertical faults increasingly offsets the terraces from a 1−2 m at low elevations (T1 and T2) to 15 ± 5 m for T10 (supplementary data, flight Tira south).

South of the NE trending faults, the lower part of the sequence includes four well-preserved coral reef terraces reaching, for T4's shoreline an elevation of 51 ± 5 m (Figs. 11B and 12). The slopes of the three lowermost terraces (T1 to T3) vary between the inner (shallow-dipping) and the outer part of the terrace (steeper-dipping). By comparison with the modern shore that we surveyed by boat and snorkelled, we interpret such variation in slope as the joint occurrence of a steeper fossil reef and of a shallow-dipping rocky shore platform carved in the limestone of T1 (see section 3.1). Sample GSL 2013-16 was drilled at 19−20 m next to T2 ′s shoreline angle (at 22 ± 3 m). The coral sample yielded a U/Th age of 304 ± 28 ka (Fig. 12A, Table 1). Within the large margin of error of our dating, we correlate the reef limestone dated to the nearest, MIS 9 (324.5 ± 18.5 ka) high-stand. Our observations suggest that the inner edge of T2 is a rocky-shore platform carved in the reef limestone of T3. Consequently, we allocated the above terrace (T3) to MIS 9.

At the southern tip of the Sampolawa Peninsula, we carried out two dGPS elevation transects (Fig. 11 B, D and E) up to elevations of 430 ± 10 m. Many terraces are morphologically continuous between both transects (in bold on Fig. 11D and E). To the sides of the Bahari embayment, the Holocene to modern notch reaches

elevations of 2.5 ± 0.5 m (see 4.2). In the middle of the bay, conversely, wave-built deposits (TH) are found up to ~5 m. In this area, TH and T1 are compound terraces probably because of reworking, and have merged into a single landform that culminates at 15 ± 2 m (Fig. 11D and E). To the centre-east of the Bahari embayment, we collected GSL 2012-36 within T1 limestone at 12−13 m, the shoreline of the terrace being at 15 ± 2 m (Table 1, Fig. 11B). GSL 2012-36 yielded an age of 112 ± 4.1 ka (Table 1) which leads us to allocate T1 to MIS 5e high-stand. We correlate T3 to MIS 9, because of the lateral continuity of the terrace toward the neighbouring dated site of southern Tira (Sample GSL 2013-16).

5. Discussion

5.1. Palaeogeographical evolution of SE Sulawesi or the elevated reef-limestone-island factory

The distribution and morphology of reefs and islands in SE Sulawesi reveal a palaeogeographic evolution that corresponds to the uplift and occasional coalescence of elevated reef limestone islands. A synthetic geomorphic scenario is proposed, based on the morphology of the islands from the Tukang Besi and Buton archipelagos (Fig. 13). The initial stage (Fig. 13A1-B1) is that of a reef platform or a table reef whose size typically ranges from a few tens of metres to tens of kilometres with various shapes: e.g., the Kapota
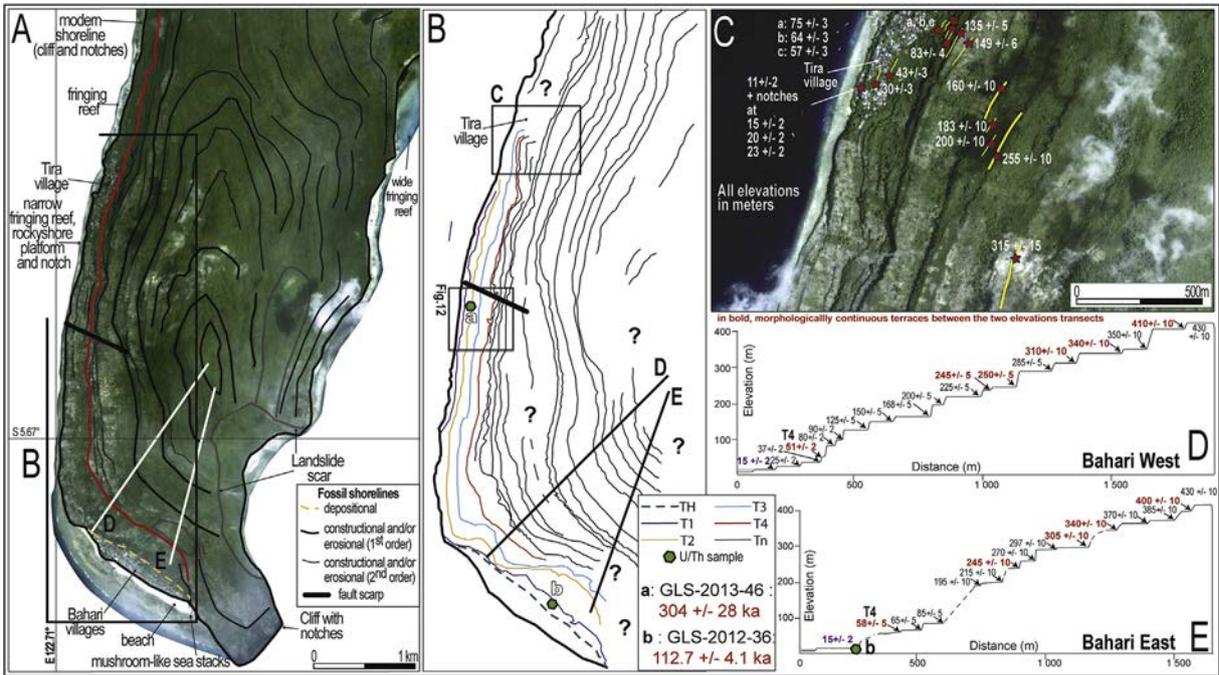

Fig. 11. A) Sequence of coral reef and marine terraces and tectonic structures in the Sampolawa peninsula. For mapping facilities, we distinguish 1st order and 2nd order strandlines. (For interpretation of the references to colour in this figure legend, the reader is referred to the Web version of this article.)

and Kaledupa reefs are large, oblong reef platforms (Fig. 7A) whereas the Koro Maha reef is more circular (Fig. 13C stage 0). The first stage consists in the uplift of a flat, low-lying coral reef island bordered by a fringing coral reef (Fig. 13A2, B2). Hoga Island is flat, ~3.5 km long and 2.5 km wide, low-lying (<20 m) and totally surrounded by a typically 1-km-wide fringing reef. To the East of Hoga Island, the modern shoreline is marked by a 1−1.5 m sea cliff associated with a narrow notch carved in the limestone of an emerged coral reef (Fig. 13 stage 1). The surface of the karstified fossil reef is at ~4 m in elevation (Fig. 13C stage 1). To the North of the island, limestones are found up to ~20 m in elevation but no clear staircase morphology (terrace) is observed. Emerging islands further expand by the formation of successive coral reef terraces that form during separate sea-level high-stands leading to one, two (stage 2 on Fig. 13) or more stages (stage n on Fig. 13). Eventually, uplifting reef platforms and/or table reefs may coalesce such as on Binongko, Wangi-Wangi or Siumpu (Fig. 13C stage 2). Tomea and Binongko islands (Figs. 1 and 7) or the SE corner of Buton Island consist in stage n elevated island (Fig. 13B). For example, Tomea includes at least 14 successive strandlines (Tjia et al., 1974). On SE Tomea, at the western tip of a ~1 km long embayment, we observed a sequence of three notches above the modern one in a 25-m-high sea cliff. We measured the elevation of the notches with the telemetry system tied to the quadcopter as well as by direct measurement by aiming a distance-meter at the flying quadcopter. The notches are found at 4 ± 0.5 m, 9 ± 1 m and 17 ± 3 m. For a photogrammetric model of the cliff, please see https://goo.gl/ULXY7Q).

Overall, the late Cenozoic progressive uplift of submarine banks and shoals first led to the formation of platforms and table reefs on top of morphological highs. Tectonic uplift subsequently allowed the development of sequences of fringing coral reef terraces to form ~30 elevated reef limestone islands (Fig. 1C). In SE Sulawesi, the slow to moderate, long lasting uplift (see sections 5.2, 5.3) resulted in highly elevated sequences, especially on S Buton (see Fig. 5)

which could, in theory (Montaggioni and Braithwaite, 2009) include terraces correlated to low-stands (Fig. 13 A3-4).

5.2. Estimates of Middle and Upper Pleistocene uplift rates

We derive both apparent and eustasy-corrected uplift rates from shoreline angle elevations of dated terraces (Table 3). Within the study area, we identified, at elevations lower than 60 m, terraces allocated to the three last interglacial periods (MIS 5e, 7, 9). At four sites, we allocated a terrace or a reef limestone unit to MIS 5e, at four sites to MIS 7 and at one site to MIS 9 (Table 1, for a probability density plot following the interglacial stages and sub-stages see Fig. 14A).

On NE Wangi-Wangi, MIS 5e apparent uplift rates are of 0.14 ± 0.02 mm yr^{-1} and eustasy-corrected uplift rates have a mean of 0.13 ± 0.11 mm yr^{-1} (Table 3, Fig. 14B). On W Kadatua, apparent MIS 5e uplift rates are of 0.29 ± 0.05 mm yr^{-1} and eustasy-corrected uplift rates have a mean of 0.28 ± 0.13 mm yr^{-1} (Table 3, Fig. 14B). In N Siumpu, apparent MIS 7 uplift rates are of 0.25 ± 0.04 mm yr^{-1} and eustasy-corrected uplift rates have a mean of 0.32 ± 0.12 mm yr^{-1}. Finally on the SE Sampolawa Peninsula, both apparent MIS 5e and MIS 9 uplift rates are of 0.12 ± 0.02 mm yr^{-1} (Table 3, Fig. 14B). Mean eustasy-corrected uplift rates since MIS 5e are 0.11 ± 0.11 mm yr^{-1} whereas MIS 9 uplift rates mean to 0.14 ± 0.09 mm yr^{-1} (Table 3, Fig. 14B).

Average apparent or eustasy-corrected uplift rates are around 0.1−0.3 mm yr^{-1}, which correspond to low to moderate rates (Classes C and B as in Pedoja et al., 2011). In SE Sulawesi, uplift rates vary in space and time as evidenced locally, for example, by the faulting and folding of the upper terraces within the Pasarwajo Gulf (Fig. 10 C, D, E). At a regional scale, at this stage of study, MIS 5e uplift rates are higher on the Kolodonale block to the NW (W Kadatua, apparent uplift rate of 0.29 ± 0.05 mm yr^{-1}) than on the Lucipara block to the SE (Wangi-Wangi apparent uplift rate of
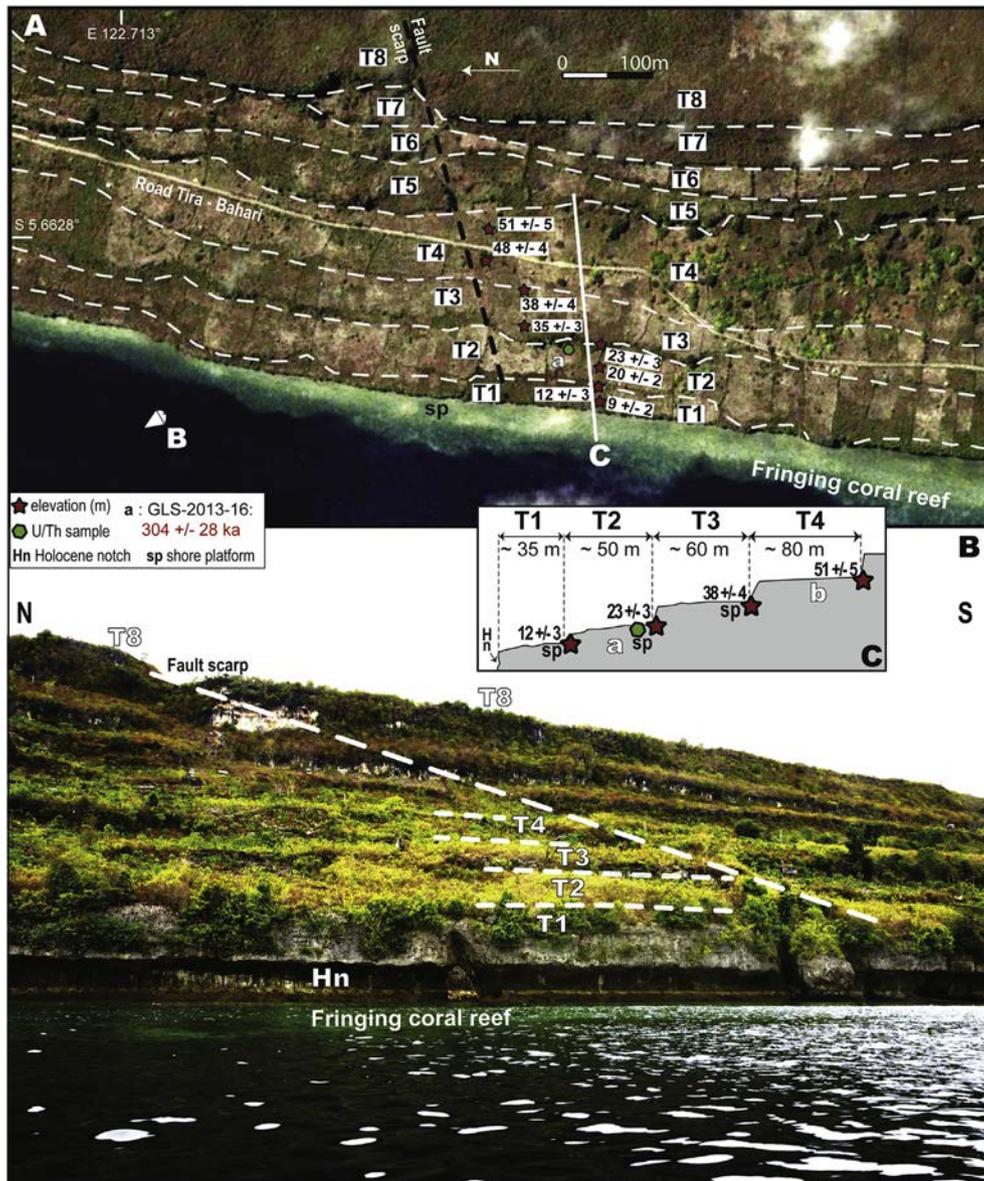

Fig. 12. Eastern Sampolawa peninsula (see location in Fig. 11). **A)** Landsat image showing the general distribution of the coral reef and marine terraces. **B)** Interpreted picture, see location on panel A. **C)** Elevation transect and dating.

$0.14 \pm 0.02 \, \mathrm{mm \, yr^{-1}}$). At a larger scale, we suggest that there is a northward decrease of coastal deformation intensity in eastern Indonesia (section 2.2 and Fig. 2).

### 5.3. Timing for the onset of some sequences from SE Sulawesi

Assuming constant uplift rates, we extrapolate the mean eustasy-corrected uplift rates to propose a possible age for the uppermost shorelines of the sequences (as in Lajoie, 1986). These extrapolations provide an indicative chronological framework that we discuss with regard to the regional geology.

Extrapolating a mean eustasy-corrected uplift rate of $0.13 \pm 0.11 \, \mathrm{mm \, yr^{-1}}$ the summit of Wangi-Wangi ($240 \pm 10 \, \mathrm{m}$) emerged between 12.5 Ma and 1 Ma with a mean of 1.9 Ma. The Tindoi fossil reef platform (~$180 +/20 \, \mathrm{m}$) emerged between 10 Ma and 0.6 Ma with a mean at 1.4 Ma. Finally, the Numana fossil reef platform (~$60 \pm 10 \, \mathrm{m}$) emerged between 3.5 Ma and 0.2 Ma (mean

at 0.5 Ma). Siumpu Island ($250 \pm 10 \, \mathrm{m}$) presents a local mean eustasy-corrected MIS 7e uplift rate of $0.32 \pm 0.12 \, \mathrm{mm \, yr^{-1}}$ which suggest emersion between 1.3 and 0.5 Ma (mean at 0.8 Ma). On Kadatua (~$100 \pm 10 \, \mathrm{m}$) the mean MIS 5e eustasy-corrected uplift rate of $0.28 \pm 0.13 \, \mathrm{mm \, yr^{-1}}$ suggests that the island could have emerged between 0.7 Ma and 0.2 Ma (mean at 0.4 Ma).

For the Sampolawa Peninsula ($430 \pm 10 \, \mathrm{m}$), in SE Buton, we extrapolated a mean eustasy-corrected MIS 9 uplift rate of $0.13 \pm 0.06 \, \mathrm{mm \, yr^{-1}}$ (uplift 1) and an uplift rate of $0.11 \pm 0.02 \, \mathrm{mm \, yr^{-1}}$ (uplift 2) obtained according to the values of Murray-Wallace and Woodroffe (2014). According to those uplift rates the onset of the 430 m high sequence on the Sampolawa Peninsula occurred between 2.2 Ma and 6.2 Ma (uplift 1) or 3.2 and 4.8 Ma (uplift 2).

These extrapolations, even with their large margins of error, are compatible with earlier estimates in this area. The Sampolawa sequence of coral reef terraces was proposed to be Plio-Quaternary

16
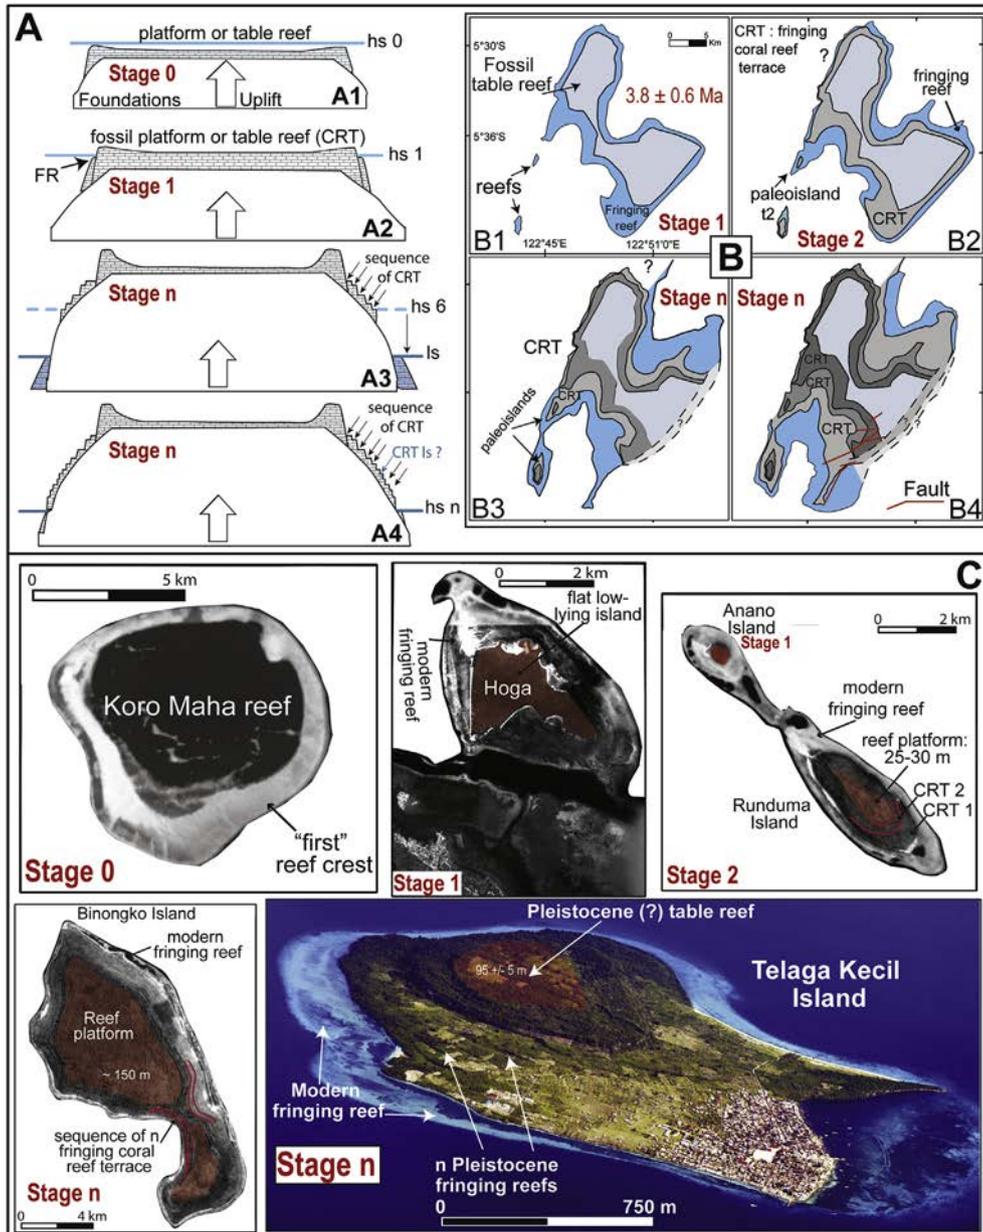

Fig. 13. Sequential formation of elevated reef limestone islands in SE Sulawesi. **A)** Schematic evolution in cross section. A reef table or platform on a bathymetric high develops during high-stand 0 (hs 0 on A1). During high-stand 1 (hs 1 on A2), a fringing reef is surrounding the fossil reef platform. The following high-stands will form successive coral reef terraces (CRT on A2). In theory, some terraces related to low-stands (ls on A3) could be preserved and integrated within the sequences (CRT ls on A4). **B)** Formation of the elevated reef limestone island of SE Buton. A table platform (B1) uplifted what resulted in its emersion (B2). Then, sequences of coral and marine terraces formed on the emerging slopes (B3) until modern times (B4). The faults are only represented for the final stage (stage n). For the age proposed on B1 see text for more details. **C)** Various stages of formation of an elevated reef island, from stage 0 to stage n from the Tukang Besi archipelago. Islands location on Fig. 1C. Aerial view of Telega-Kecil Island (location Fig. 1B); stage n.

as early as in the beginning of 20th century (Verbeek, 1908). Chronological constraints on microfossils from the limestones of the terraces (i.e., the Wapulaka Formation see Settings) led previous authors (Fortuin et al., 1990; Satyana and Purwaningsih, 2011) to suggest that the sequence is bracketed between the planktonic foraminifera zones N21 (4.4 Ma to 1 Ma) and N22/23 (from 1 Ma onwards, Gradstein et al., 2012). Consequently, we postulate that the sequences of S Buton cannot be older than 4.4 Ma., and thus, we consider that the Sampolawa Peninsula most probably emerged between 4.4 and 3.2 Ma (~3.8 ± 0.6 Ma). We stress out here that the sequence including more than 40 terraces found up to 650 m, to the North of the Sampolawa Peninsula, next to Pasarwajo, could constitute an even longer record of Plio-Quaternary sea level.

5.4. Comparison with other long-lasting emerged sequences of fossil coral reefs

For their abundant shorelines (>40), the sequences from SE Buton only compare to the sequence of Chala Bay (Peru), which includes 27 successive erosional and depositional shorelines (Goy et al., 1992). Excluding sequences of depositional strandlines (beach-ridges sequence), at a global scale, only 58 described sequences include more than 10 successive marine terraces (Pedoja et al., 2014). Sequences including numerous terraces are found in various geodynamical settings. Their formation is not related directly to uplift rates: they are present in subsiding areas (Hawaii Island; Szabo and Moore, 1986; Ludwig et al., 1991; Webster et al.,

17

18

2009; Puga-Bernabéu et al., 2016) or on fast uplifting coasts (Huon Peninsula, Papua New Guinea; Bloom et al., 1974; Chappell, 1974).

Long-lasting Late Cenozoic sequences of elevated reefs represent valuable sea level records through the construction of successive limestone units. Such sequences are described within the Caribbean (Haiti, Cuba, Barbados) and Indo-Pacific province (Ryukyu, Makatea, Austral, Cook, Sumba or Alor) (Pedoja et al., 2014, Fig. 15). The coastal sequences from SE Sulawesi constitute an intermediary step between the relatively young (1 Ma on Sumba or Barbados), including numerous successive terraces (18 at Cape Laundi, Sumba), emerged sequences from Sumba, Alor or Barbados and the older and more degraded record of Mahé, Futuna, or Makatea. At the latter sites, only 1 to 6 terraces are present below the limestone constituting the upper table reef or atoll generally composed of early Pleistocene or older fossil reefs (Fig. 15). This intermediary step represents one of the most comprehensive records of sea level high-stands for the Quaternary and possibly part of Pliocene times.

5. Conclusions

The Late Cenozoic evolution of SE Sulawesi corresponds to the uplift of a rough sea floor that resulted in the formation of spectacular coastal sequences present on 23 islands. Based on 13 U/Th and 7 ^{14}C ages, we allocated coral terrace (or reef limestone unit) to the last interglacial periods (MIS 1, 5e, 7, and 9a). MIS 5e terraces (122 ± 6 ka) are found at elevations lower than 20 m, except on Kadatua (34 ± 5 m). On SE Buton, an undated sequence includes more than 40 successive terraces and reaches 650 m in elevation. On the neighbouring Sampolawa Peninsula, 18 successive terraces culminate at 430 ± 10 m and include MIS 5e and 9 terraces at elevations below 40 m. Extrapolation of eustasy-corrected Middle Pleistocene low uplift rates (0.14 ± 0.09 mm yr^{-1}) combined with constraints from local geology suggest that the onset of the sequence on Sampolawa Peninsula started at 3.8 ± 0.6 Ma. These sequences therefore correspond to the longest and most comprehensive records of Plio-Quaternary sea level high-stands to date.
