Abstract:

Development of a sensitive and reliable method towards detection of hydrogen peroxide (H_2O_2) is important for biomedical and environmental applications. The preparation of electrochemical sensors with high selectivity and sensitivity toward H_2O_2 using porous homeotypic bi-metallic $\text{Ce}_{1-x}\text{Tb}_x\text{O}_y$ crystals is reported. The porous homeotypic bi-metallic $\text{Ce}_{1-x}\text{Tb}_x\text{O}_y$ crystals are prepared by direct pyrolysis of $\text{Ce}_x\text{Tb}_{1-x}$ -MOFs precursors. The porous homeotypic bi-metallic $\text{Ce}_{1-x}\text{Tb}_x\text{O}_y$ crystals are deposited on glassy carbon electrodes, and subsequently apply for detection of H_2O_2 in an alkaline media. The porous $\text{Ce}_{1-x}\text{Tb}_x\text{O}_y$ layers show high stability, high sensitivity toward H_2O_2 ($1.6831 \mu\text{A}\cdot\text{Mm}^{-1}$) ($12.99 \mu\text{A}\cdot\text{mM}^{-1}\cdot\text{cm}^{-2}$) in a broad linear range ($0.1 \mu\text{M}$ - 4.2 mM) with a detection limit of $7.7 \mu\text{M}$ ($\text{S/N} = 3$), and fast response (less than 10 s).

Keywords: Sensor; Hydrogen peroxide; Porous homeotypic bi-metallic $\text{Ce}_{1-x}\text{Tb}_x\text{O}_y$; MOFs; Density function theory

1. Introduction

Hydrogen peroxide (H_2O_2), as a by-product of aerobic metabolism of enzymatic reactions, is widely applied in semiconductor, plastic, and food industry. It is well known that the H_2O_2 is low-toxic but easily damage lipids, proteins and carbohydrates. It can even cause cancer on account of its oxidizing capability when accumulating to a certain amount in human body [1]. Therefore, the development of a sensitive and reliable method to determine the H_2O_2 is important for biomedical and environmental applications.

Up to now, many techniques have been used to detect H_2O_2 , including spectrophotometry [2,3], chemiluminescence [4-7], fluorometry [8-11], titrimetric, and electrochemistry [12-16]. Especially, the electrochemical approach with high sensitivity and easy handling, is receiving more attention during the last decades. It is well known that electroactivity mainly depends on electrode modified materials. Enzyme as a common electrode modified material, is fast, sensitive and simple for H_2O_2 detection, but its stability is strongly affected by variation of the pH, temperature and concentration of analyte. Therefore, significant attention is focused on the fabrication of stable nonenzymatic sensor for H_2O_2 . Precious metals (*e.g.* gold, silver, platinum, and rhodium) as active electrode modifier materials show great stability and sensitivity in the detection of H_2O_2 [17-19]. However, the high price limited their application. Recently, metal oxides (*e.g.* Co_3O_4 , MnO_2 , Fe_2O_3 , TiO_2 , and CeO_2) were used for detection of H_2O_2 [20-23]. Among them, CeO_2 has been widely

used in biology, medicine and catalysis owing to its effective catalytic activity and free radical scavenging properties [24-26]. Particularly, the existence of a highly flowing lattice oxygen defect in the CeO₂ lattice contributed to the Ce³⁺ and Ce⁴⁺ conversion on the surface [27]. Besides, other properties like high surface area, biocompatibility, chemical stability, electrocatalytic and oxygen storage capacity significantly improve the performance of electrochemical sensors. Such as, Jha et al [28]. reported a novel synthesis approach of CeO₂/reduced graphene oxide (rGO) xerogel composite to monitor H₂O₂ by taking advantage of a sol-gel route consisting of CeO₂ nanoparticles anchored rGO nanosheets, which enhanced the detection performance towards H₂O₂. Wei Zhang and his colleagues [29] prepared Au/CeO₂-chitsan composite films by one-step synthesis approach for H₂O₂ sensing. The composite films show excellent response to H₂O₂ and high stability. Although tremendous efforts have been made in H₂O₂ electrochemical sensors, the selectivity and sensitivity of the existing materials still need to be improved.

In an attempt to address such difficulty of electrocatalytic performance of sensor device, two major issues have been considered. Firstly, a homeotypic bi-metallic co-existing material with two metals evenly distributed are required to observe their synergistic effect compared with other complex metal oxides. Secondly, porous material is expected to improve substantially the electrochemical performance and efficiency of the electrocatalytic device. Porous materials have well-defined channel connectivity, which could be

beneficial to shorten diffusion path and increase mass transfer efficiency. Moreover, porous material provides more effective surface area for electrochemical reaction, and allow better reaction kinetics at the electrode surface. However, to our best knowledge, there are few reports on the preparation of porous homeotypic bi-metallic co-existing oxide layers so far. Therefore, exploration of facile method is the key point for the fabrication of porous homeotypic bi-metallic co-existing oxide material. We notice that the metal-organic frameworks (MOFs) are the classic materials with highly order porous, metal sites, and ultrahigh surface area. Moreover, the synthesis of metal-based functional materials derived from MOFs precursors has also drawn great attention from researchers worldwide [30]. The materials derived from MOF precursors will inherit properties of MOFs, implying that MOFs is a promising precursor to prepare porous homeotypic bi-metallic co-existing oxide.

In this work, a series of mono-metallic and homeotypic bi-metallic co-existing materials ($\text{Ce}_{1-x}\text{Tb}_x\text{O}_y$) were prepared by controlling the thermal decomposition conditions of $\text{Ce}_{1-x}\text{Tb}_x\text{-MOF}$ precursor, and the resulted new porous materials were applied for preparation of selective chemical sensors towards H_2O_2 .

2. Experimental

2.1 Materials and Chemicals

Cerium (III) nitrate hexahydrate ($\text{Ce}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$), terbium nitrate hexahydrate ($\text{Tb}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$), N, N-dimethylformamide (DMF), sodium acetate anhydrous

(CH₃COONa), hydrogen peroxide (H₂O₂, 30%, w/w), 1,3,5-Benzenetricarboxylic acid (BTC) were purchased from Fluka. Sodium phosphate (NaH₂PO₄·2H₂O and Na₂HPO₄·12H₂O), chitosan (C₆H₁₁NO₄)_n and glutaraldehyde solution (C₅H₈O₂, 25%, w/w) were purchased from Sinopharm Chemical Reagent Co., Ltd. All chemicals were used without further purification.

2.2 Preparation of Ce_{1-x}Tb_x-MOF crystals

Ce_{1-x}Tb_x-MOF crystals were synthesized following the procedure, according to our previous reports [31]. In a typical synthesis for the Ce_{0.9}Tb_{0.1}-MOF material, Cerium (III) nitrate hexahydrate (46.8 mg), terbium nitrate hexahydrate (5.4 mg) and Trimesic acid (H₃BTC) (20 mg,) were dissolved in 10mL of Dimethylformamide (DMF) and 2 mL of deionized water. Then solution was added into Sodium Acetate (CH₃COONa) (25 mg) under vigorous stirring at ambient temperature (~25 °C) for 10 min resulting in white crystals with a crystalline yield of 76% (based on H₃BTC). The products were isolated by repeated centrifugation and washing with deionized water and DMF for several times. Finally, the products were dried in air at 60 °C.

2.3 Preparation of Ce_{1-x}Tb_xO_y crystals

The Ce_{1-x}Tb_xO_y crystals were prepared by pyrolysis of the as-synthesized Ce_{1-x}Tb_x-MOF crystals at 400 °C in air for 2 hours with a heating rate of 2 °C/min (the framework of the Ce_{1-x}Tb_x-MOF crystals begins to collapse at 350 °C).

2.4 Preparation of Ce_{1-x}Tb_xO_y-modified glassy carbon electrode (GCE)

In order to study the electrochemical behaviour of the Ce_{1-x}Tb_xO_y crystals, they were

deposited on a bare glassy carbon electrode (GCE). The GCE were pre-treated by polishing with a slurry of 0.05 mm alumina particles in order to create a mirror finish surface, and then sonicated in absolute ethanol and de-ionized water for 5 min. The GCE was rinsed thoroughly with de-ionized water and then dried at ambient temperature. Biopolymer chitosan (CHT) was used as an immobilization matrix to attach the $\text{Ce}_{1-x}\text{Tb}_x\text{O}_y$ crystals on the GCE surface. A mixture of chitosan and $\text{Ce}_{1-x}\text{Tb}_x\text{O}_y$ crystals was prepared by adding 10 mg $\text{Ce}_{1-x}\text{Tb}_x\text{O}_y$ in 0.5 L chitosan (0.25% prepared in 0.1 M acetic acid), and then subjected to ultrasonic agitation for 30 min. The $\text{Ce}_{1-x}\text{Tb}_x\text{O}_y$ crystals were prepared from the $\text{Ce}_{1-x}\text{Tb}_x$ -MOF precursor (see previous section). 10 μL of this mixture was cast onto the GCE surface and subjected to drying. Then the electrode was incubated with 2.5% glutaraldehyde for 10 min to crosslink the chitosan in order to increase the stability of the layer. The electrode was thoroughly rinsed with distilled water and dried in air to use.

2.5 Characterization

The structure and morphology of the as-prepared samples were characterized with a field emission scanning electron microscope (SEM) (Hitachi Limited S-4800 operating at 5 kV and JEOL JSM-7900F operating at 0.8 kV. High-resolution transmission electron microscopy (HRTEM) and the corresponding energy dispersive spectroscopy (EDS) mapping analyses were performed using a JEOL JEM-2100F microscope at an acceleration voltage of 200 kV. The powder X-ray diffraction (PXRD) patterns were collected on a Siemens D5005 diffractometer with $\text{Cu K}\alpha$ radiation ($\lambda = 1.5418 \text{ \AA}$). The infrared spectra (IR)

were measured with a NEXUS FT-IR using the KBr technique. Thermal gravimetric analysis (TGA) was performed on a Perkin-Elmer TGA thermogravimetric analyser in the temperature range of 25~800 °C under nitrogen atmosphere with a heating rate of 10 °C/min. N₂ adsorption/desorption isotherms were recorded at -196 °C on an ASAP 2020 Micromeritics instrument (before measurement, all samples were degassed at 200 °C overnight). X-ray photoelectron spectrum (XPS) analysis was carried out using a PH 5000 Versaprobe system using monochromatic Al K α radiation ($h\nu = 1486.6$ eV). All binding energies were calibrated using the C 1s peak (284.8 eV). The electrochemical tests were carried out *via* an electrochemical analyzer (CHI660D, Chen hua, China). A conventional three-electrode cell was used with a saturated calomel electrode (SCE, saturated KCl) as a reference electrode, a platinum wire as counter electrode, and a bare or modified GCE (2 mm in diameter) as working electrode. Freshly prepared phosphate buffer (PB, 0.1 M, pH 7.4~8) solution was used as the supporting electrolyte. All electrochemical studies were performed under nitrogen atmosphere.

2.6 Theoretical Calculations

Theoretical calculations were performed using Vienna ab initio simulation packages (VASP) based on density functional theory (DFT) [32]. The core and valence electrons were described by the projector augmented wave (PAW) pseudopotentials. The generalized gradient approximation (GGA) proposed by Perdew, Burke, and Ernzerhof (PBE) was adopted to express the exchange correlation interactions with a cutoff energy

of 400 eV, while the van der Waals effect was accounted by the DFT-D2 method of Grimme with a 50 Å cutoff radius for pair interactions [33,34]. The fully relaxed lattice constants $a = 5.41$ Å, $b = 5.41$ Å and $c = 5.41$ Å for CeO₂. A $2 \times 2 \times 3$ supercell with a 15 Å vacuum region was used to simulate the adsorption. The convergence of energy and forces were set to 1×10^{-4} eV and 0.02 eV Å⁻¹, respectively. The Brillouin zone was sampled by the Monkhorst-Pack method with a $3 \times 3 \times 1$ k-point grid. The adsorption energy is defined as $\Delta E = E_{(\text{substrate} + \text{adsorbate})} - E_{\text{substrate}} - E_{\text{adsorbate}}$. The formation energy of oxygen vacancy was calculated by the following equation: $E_f = E_{\text{tot}}^P - E_{\text{tot}}^O + \mu_o$ where E_{tot}^P and E_{tot}^O are total energy of the pristine supercell and the supercell with O vacancy, respectively; μ_o is the chemical potential of isolated oxygen atom.

3. Results and discussion

3.1 Properties of Ce_{1-x}Tb_x-MOF crystals

For the preparation of homeotypic bi-metallic MOF (Ce_{1-x}Tb_x-MOF crystals), lanthanides metals (Ce and Tb) were selected. The Ce_{1-x}Tb_x-MOF crystals further used as a precursor is constructed from Ce and/or Tb and a rigid organic linker BTC through coordination bonding (Fig. 1). The Ce_{1-x}Tb_x-MOF has a tri-dimensional framework with a space group $P4_322$. Each building unit contains one seven-coordinated lanthanide ion (Ce and/or Tb), one BTC ligand and one water molecule; the lanthanide ion is coordinated with six oxygen atoms from six carboxylate groups of BTC ligands and one oxygen atom from a terminal water molecule (Fig. S1a) [35].

The homeotypic bi-metallic $\text{Ce}_{1-x}\text{Tb}_x\text{-MOF}$ crystal structure was confirmed by XRD (Fig. S1b). The $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{-MOF}$ is representative of the $\text{Ce}_{1-x}\text{Tb}_x\text{-MOF}$ series samples in this manuscript. The XRD diffraction peaks of the $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{-MOF}$ sample correspond to the mono-metallic Ce-MOF structure, in addition, no other crystal phase is detected. From the SEM picture of $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{-MOF}$ (Fig. S1d), highly dispersed and uniform micron-sized rod-shaped crystals with a length and width of $3\mu\text{m}$ and 500 nm , respectively are seen. The size of the $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{-MOF}$ is comparable with the Ce-MOF (Fig. S1c).

3.2 Properties of $\text{Ce}_{1-x}\text{Tb}_x\text{O}_y$ crystals

The $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{O}_y$ crystals prepared from the $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{-MOF}$ precursor under pyrolysis at $400\text{ }^\circ\text{C}$ in air atmosphere were characterized by XRD. As shown in Fig. 2a, the peaks at 28.5° , 33.2° , 47.6° , 56.4° , 59.1° and 69.5° 2θ correspond to the (111), (200), (220), (311), (222), and (400) planes of CeO_2 , which indicates that the $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{-MOF}$ precursor has been fully transformed to $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{O}_y$ [36,37]. The XRD pattern of $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{O}_y$ is exactly the same as for the CeO_2 (Fig. S3a) implying that the bi-metallic crystals have been inherited from the MOF precursor. The similar properties of homeotypic elements such as atomic radius, number and weight result in highly stable $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{O}_y$ framework.

The transformation process from $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{-MOF}$ to $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{O}_y$ was followed by FT-IR and TGA. The IR spectrum of $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{-MOF}$ (Fig. S1e) contains three peaks including asymmetric stretching vibration of the carboxyl group at $1590\sim 1480\text{cm}^{-1}$, symmetric stretching vibration of the carboxyl group at 1381cm^{-1} .

¹, and C-C vibration of the aromatic ring at 1441 cm⁻¹. These peaks disappear in the Ce_{0.9}Tb_{0.1}O_y sample (Fig. S4a), indicating that Ce_{0.9}Tb_{0.1}-MOF skeleton structure collapsed [38]. In addition, the stretching vibration of Ce-O and Tb-O bonds at 556 cm⁻¹ originating from the Ce_{0.9}Tb_{0.1}-MOF can be clearly observed in Fig. S1e. This peak completely disappeared after pyrolysis, which demonstrates that the Ce_{0.9}Tb_{0.1}-MOF has been completely transformed to Ce_{0.9}Tb_{0.1}O_y [39]. The thermal properties of Ce_{0.9}Tb_{0.1}-MOF were characterized by TG, as shown in Fig. S4b. Sample Ce_{0.9}Tb_{0.1}-MOF exhibits two weight losses in the temperature range 50~600 °C, corresponding to the weight loss (19.2 - 21.0%) attributed to the loss of physically absorbed water below 180 °C, and the weight loss (33 - 38%) due to the decomposition of the organic ligand (BTC) in the temperature range 350~400 °C. After decomposition, the remaining material is Ce_{0.9}Tb_{0.1}O_y. The thermogravimetric analysis shows that the Ce_xTb_{1-x}-MOF crystals have great thermal stability. The CeO₂ has similar properties to the Ce_{0.9}Tb_{0.1}O_y as shown by FT-IR (Fig. S3b) and TG (Fig. S3c) characterizations.

The SEM pictures of Ce_{0.9}Tb_{0.1}O_y crystals are presented in Fig. 2b. The rod-like morphology of the Ce_{0.9}Tb_{0.1}O_y-MOF precursor is well preserved after heat treatment. The crystals length and width are 2 μm and 250 nm, respectively. In comparison to the Ce_{0.9}Tb_{0.1}-MOF precursor (Fig. S1d), the Ce_{0.9}Tb_{0.1}O_y crystals decrease in size, moreover, they contain visible pores of 100 nm located on the particles surface (Fig. S2). It can be speculated that in the initial stage of pyrolysis, uniform nanoparticles of bi-metallic oxide with the organic ligand (BTC) are

formed. Subsequently, these unstable bi-metallic oxide nanoparticles are aggregated and formed micronsized $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{O}_y$ crystals (Ostwald ripening) with a large number of holes appearing on their surface. Based on the above results, the formation mechanism of the porous micronsized $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{O}_y$ is proposed, and it proceeds *via* a two-step process, as depicted in Fig. 2e. As shown, large amount of high-energy unstable bi-metallic oxide nanoparticles were obtained within a very short time (Fig. 2e: step 1). Due to the Ostwald ripening, these nanoparticles continuously aggregate into micronsized 3D superstructures (Fig. 2e: step 2). Most importantly, mesopores and macropores are formed during the formation of the bi-metallic oxide, which could be beneficial to shorten diffusion path and increase mass transfer efficiency. Moreover, the porous structure of the bi-metallic oxides would provide more effective surface area for electrochemical reaction, and will allow faster reaction kinetics at the electrode surface. SEM (Fig. S3e) and TEM (Fig. S3f) pictures of CeO_2 show great similarities to sample $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{O}_y$.

The N_2 isotherm (Fig. 2c) recorded from the $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{O}_y$ sample is a Type-IV with a H3-type hysteresis loop, which is indicative for the presence of meso- and macro-pores in the crystals. These results are consistent with SEM analysis. A detailed comparison of samples $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{O}_y$ and CeO_2 is presented in Table S2. The surface area and pore volume for $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{O}_y$ are $105 \text{ m}^2 \cdot \text{g}^{-1}$ and $0.12 \text{ cm}^3 \cdot \text{g}^{-1}$, respectively. In comparison, the surface area and pore volume of CeO_2 are $94 \text{ m}^2 \cdot \text{g}^{-1}$ of $0.11 \text{ cm}^3 \cdot \text{g}^{-1}$, respectively. The bi-metallic $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{O}_y$ sample shows

slightly higher surface area and pore volume in comparison to the CeO_2 , which is expected to provide more accessible catalytic sites and easier diffusion. The scanning transmission electron microscope (STEM) and energy-dispersive X-ray spectroscopy (EDS) images (Fig. 2d) reveal that O, Ce, and Tb are homogeneously distributed within the $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{O}_y$ crystals. The Ce/Tb ratio of 9:1 for the bulk sample is derived from the EDS.

The chemical state of the components in both samples ($\text{Ce}_{0.9}\text{Tb}_{0.1}\text{O}_y$ and CeO_2) was investigated by XPS. In Fig. 3a, the binding energy of Ce 3d_{5/2} peak for the $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{O}_y$ is located at 881.38, 887.6, and 897.4 eV, while the corresponding binding energy for the CeO_2 is measured at 882.3, 888.1, and 898.4 eV. As shown, the binding energy for the $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{O}_y$ crystals obviously decrease. The systematic energy shift due to the electronic cloud density increase, indicating that in the preparation process of $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{-MOF}$, the Tb indeed enter into the $\text{La-(1, 3, 5-BTC)(H}_2\text{O)}_6$ lattice. After heat-treatment, the Ce and Tb coexist in the oxide crystals by chemical bonding instead of mechanical mixing of two oxides. Moreover, the high-resolution spectrum of Ce 3d contains two peaks corresponding to Ce^{3+} (u) and Ce^{4+} (v) [40]. The Ce^{3+} content in samples CeO_2 and $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{O}_y$ is 31% and 40%, respectively. Three peaks at 528.6, 530.8, and 532.5 eV labelled as Q_L , Q_V , and Q_A are appeared in the $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{O}_y$ O1s XPS spectrum, which can be attributed to lattice oxygen, oxygen, and surface-adsorption species (Fig. 3b) [45.46]. The corresponding binding energy for CeO_2 is primarily centered at 529.3, 531.2, and 532.7 eV. The bonding energy of $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{O}_y$ exhibits obvious decrease in comparison with CeO_2 . Apparently, the relative

percentages of Ov in the $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{O}_y$ crystal (20%) is higher than that in the CeO_2 crystal (15%). The Ce^{3+} keep the electrostatic equilibrium and produce flowing lattice oxygen defects, namely, the Ce^{3+} can accelerate the electron transfer rate and thus improve the electrochemical activity [41]. Notably, the Ce^{3+} content in the $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{O}_y$ is more than that in the CeO_2 . It demonstrates that the Tb ions can attribute to produce Ce^{3+} . Therefore, it is expected that the $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{O}_y$ will be more efficient than the CeO_2 in electrochemical reactions.

3.3 Electrochemical activity of $\text{Ce}_{1-x}\text{Tb}_x\text{O}_y$ toward H_2O_2

The influence of the Ce/Tb ratio of the materials on electrochemical performance was studied by cyclic voltammetry. The $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{O}_y$ modified GCE (sample abbreviated as GCE- $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{O}_y$), shows the strongest redox peak (Fig. S5), and the redox peak decreases gradually along with the increase of the Tb content. The cyclic voltammetry results show that the Ce/Tb ratio of 0.9 is optimal for H_2O_2 detection. Therefore, the $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{O}_y$ crystals were selected for further electrochemical characterization. The cyclic voltammetry (CV) curves for the three samples, *i.e.*, blank GCE, GCE- CeO_2 , and GCE- $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{O}_y$ before and after addition of 10 mM H_2O_2 are depicted in Fig. 4a and b. All three samples do not show any redox peak in phosphate buffered solution (PBS) prior addition of H_2O_2 . After adding the H_2O_2 , the reference electrode (GCE) shows a weak peak at 0.9 V. While the GCE- CeO_2 sample (Fig. 4a) exhibits a wide peak at 0.45 V representative for the detection of H_2O_2 . The surface reaction process can be represented by the following equations [42-44],

In comparison, the GCE-Ce_{0.9}Tb_{0.1}O_y shows a wide peak at same potential point (Fig. 4b) but the peak current increases by 60%, which can be attributed to that the synergy of Tb and Ce leading to improved detection. To evaluate the detection limit, sensitivity, and the linear range of the GCE-Ce_{0.9}Tb_{0.1}O_y, the measurements were performed with different concentration of H₂O₂; the amperometric response at 0.75V in 0.1 M PBS solution with continuous addition of H₂O₂ was measured. The current value (95%) reach steady state within 8s, indicating that the sensor responds quickly to H₂O₂, and the current increases alone with the increase of the H₂O₂ concentration (Fig. 4c-f). For the GCE-CeO₂, the linear range is 0.2 to 4.2 mM (the calculated curve is $I_{\text{Pa}} (\mu\text{A}) = 0.7748 C (\text{mM}) + 0.4237$ ($R^2 = 0.9991$)), the sensitivity is 0.7748 $\mu\text{A} \cdot \text{mM}^{-1}$ ($6.17 \mu\text{A} \cdot \text{mM}^{-1} \cdot \text{cm}^{-2}$, $R^2 = 0.9991$), and the detection limit is 17 μM ($S/N = 3$) (Fig. 4c and d). The amperometric response of the GCE-Ce_{0.9}Tb_{0.1}O_y is shown in Fig. 4e and f. The current intensity for the GCE-Ce_{0.9}Tb_{0.1}O_y is 1.5 times higher than for the GCE-CeO₂. The linear range, sensitivity and detection limit are 0.1 to 4.2 mM ($I_{\text{Pa}} (\mu\text{A}) = 1.6318 C (\text{mM}) + 2.012$ ($R^2 = 0.9999$)), 1.6318 $\mu\text{A} \cdot \text{mM}^{-1}$ ($12.99 \mu\text{A} \cdot \text{mM}^{-1} \cdot \text{cm}^{-2}$, $R^2 = 0.9999$) and 7.7 μM ($S/N = 3$), respectively. The results

show that the GCE-Ce_{0.9}Tb_{0.1}O_y has higher capacity towards H₂O₂ detection in comparison to the GCE-CeO₂. An evaluation of the performance of the current sensor (GCE-Ce_{0.9}Tb_{0.1}O_y) with those described in the literature is presented in Table S3. The sensitivity, detection limit and linear range of the GCE-Ce_{0.9}Tb_{0.1}O_y sensor for H₂O₂ are higher in comparison with those reported in the open literature. The great performance of the GCE-Ce_{0.9}Tb_{0.1}O_y sensor for H₂O₂ is due to the following two reasons: Firstly, the Tb in the La-(1, 3, 5-BTC) H₂O)₆ structure is chemically bonded and thus lead to synergy between Ce and Tb in the Ce_{0.9}Tb_{0.1}-MOF. After pyrolysis, the Ce_{0.9}Tb_{0.1}O_y inherited the synergy between Ce and Tb from MOFs precursor. It can produce more Ce³⁺, and increases the concentration of oxygen vacancies in the lattice, thus accelerating the conduction rate of the charge, which promotes the electrode surface rapid catalytic reaction. Secondly, the uniform crystals in size with regular pores are beneficial to shorten diffusion path and increase mass transfer efficiency. Thus the porous Ce_{0.9}Tb_{0.1}O_y crystals provide more effective surface area for electrochemical reaction, and allow faster reaction kinetics at the electrode surface.

The Fig. S6a shows a response curve of CV (Cyclic Voltammetry) measurements in 10 Mm H₂O₂ solution. All curves coincide well after 30 cycles sweep in the voltage range of -1.5V-1.5V, indicating that GCE-Ce_{0.9}Tb_{0.1}O_y shows high stability for H₂O₂. In addition, the selectivity of GCE-Ce_{0.9}Tb_{0.1}O_y was tested. 0.3 mM H₂O₂, 0.1 mM glucose, 0.3 mM H₂O₂, 0.1 mM ascorbic acid,

0.3 mM H₂O₂, 0.1 mM urea, 0.3 mM H₂O₂, 0.1 mM sucrose, 0.3 mM H₂O₂, and 0.1 mM citric acid were sequentially added during the amperometric test. From Fig. S6b it can be seen that response current generated by adding H₂O₂ is obvious. However, response current is weak and the interference can be ignored when others substance was injected into PBS, indicating that GCE-Ce_{0.9}Tb_{0.1}O_y exhibited good selectivity for H₂O₂.

Further understanding of the intrinsic property and reactivity of Ce_{0.9}Tb_{0.1}O_y crystals together with the adsorption phenomena of the H₂O₂ were studied by density functional theory (DFT). The most thermodynamically stable (111) surface was selected and presented in Fig. S7. While all possible active sites were investigated and show in Fig. S8. Compared with pure CeO₂ model, the adsorption energy of H₂O₂ on Ce_{0.9}Tb_{0.1}O_y model decrease from -0.99 eV to -2.48 eV, and the O-H band of H₂O₂ increases from 1.01 Å to 1.59 Å, indicating that the adsorption of H₂O₂ is more favorable on Ce_{0.9}Tb_{0.1}O_y model (Fig. 5a and b). The larger absolute adsorption energy for H₂O₂ on Ce_{0.9}Tb_{0.1}O_y model prove the detected substance is more easily adsorbed on the adsorbent, and the electrode material has higher sensitivity and lower detection limit to the substance H₂O₂. Our calculations agree well with the experimental results. When Ce is substituted by Tb possessing higher electron negativity ($x = 1.20$) than that of Ce ($x = 1.12$), thus Ce can readily donate more electrons to the O atoms, yielding some electron-positivity and electron-negativity cations on Ce and O, respectively (Fig. S9). This result was further confirmed by Bader analysis. As a result, the O and H atom of H₂O₂ can favor asorbtion on the neighbor Ce and O surrounding Tb, respectively. The

DFT calculations suggest that the synergistic effect between Ce and Tb can further trigger the intrinsic activity of the as-prepared $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{O}_y$ electrodes. Moreover, Fig. 5c and d indicate that the CeO_2 model with oxygen defects exhibits a narrow band gap of 1.25 eV in comparison with pristine CeO_2 (1.93 eV), confirming the improvement of the intrinsic electron transfer capacity by introduction of Ce^{3+} . The formation energy of oxygen vacancy for CeO_2 and $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{O}_y$ are -0.63 and -0.82 eV, respectively, indicating that the oxygen vacancy is facilitated by Tb incorporation (Fig. S10). This result proves the increased concentration of oxygen vacancies in the $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{O}_y$, which is in agreement with XPS results shown above.

4. Conclusion

Porous $\text{Ce}_{1-x}\text{Tb}_x\text{O}_y$ crystals are prepared through direct pyrolysis of homeotypic bi-metallic $\text{Ce}_{1-x}\text{Tb}_x\text{-MOF}$ precursors. The porous $\text{Ce}_{1-x}\text{Tb}_x\text{O}_y$ crystals deposited on glassy carbon electrodes were used for detection of H_2O_2 in alkaline solutions. The glassy carbon electrodes covered with $\text{Ce}_{0.9}\text{Tb}_{0.1}\text{O}_y$ crystals exhibited high stability, high sensitivity toward H_2O_2 ($1.6831 \mu\text{A}\cdot\text{Mm}^{-1}$) ($12.99 \mu\text{A}\cdot\text{mM}^{-1}\cdot\text{cm}^{-2}$) in a broad linear range (0.1 μM - 4.2 mM) with a detection limit of 7.7 μM ($\text{S/N} = 3$), and fast response (less than 10 s). The synergy between Tb and Ce proves the detected substance is more easily adsorbed on the adsorbent, which enhances the electrochemical behaviour remarkably. Besides, the well-defined pores connectivity attributed to the improved reaction efficiency. This new concept presented here paves the way to efficient sensing of H_2O_2 using porous homeotypic bi-metallic materials.
