HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L’archive ouverte pluridisciplinaire HAL, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d’enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.
This study is concerned with the design of a Mueller imaging polarimeter for the visualization of spatially-varying Mueller matrix fields. A simplified calibration procedure is advocated, where all the optical elements are calibrated simultaneously rather than independently as in the state-of-the-art. This is shown to significantly reduce the bias inherent to sequential calibration methods. In addition, this procedure requires no reference sample, it allows calibration both in transmission or in reflection modes, and it relies on ready-to-use cameras. Put together, these novelties should help non-specialists in optics designing and calibrating a Mueller imaging polarimeter for applications such as material classification. © 2019 Optical Society of America. The polarization properties of a medium can be measured through Mueller polarimetry [1], and have proven to be of fundamental importance in many applications such as biomedical diagnosis [2] or material classification [3]. Although the design and calibration of a Mueller polarimeter has long been investigated in the Optics community, most of existing works focus on the accurate measure of a single Mueller matrix, using e.g. a HgCdTe photodetector [4] or a photodiode [5]. On the other hand, practitioners need two-dimensional visualizations of the Mueller matrix field, in order to identify spatially-varying properties. Yet, non-specialists in Optics would probably favor a solution based on commercial cameras, which requires no reference sample [6] or post-processing to remove calibration errors [7–10], and which can handle both transmission and reflection modes [11]. Calibration procedures that meet such requirements do already exist [5, 12] but they consider a dedicated calibration procedure for each optical element. One objective of this study is to show that one should rather simultaneously calibrate all the optical elements, for the sake of both simplicity and accuracy. Overall, this results in an easy-to-implement calibration procedure which simultaneously meets all the aforementioned requirements, and should hopefully help non-specialists in Optics in the design of a Mueller imaging polarimeter.

![Fig. 1. Polarimeter used in our experiments, comprising a Kohler illumination (blue), a PSG (cyan) consisting of a polarizer \( p^G \) and a retarder \( R^G \), a medium \( M \) to be analyzed (white), a PSA (yellow) consisting of a retarder \( R^A \) and a polarizer \( P^A \), and a CCD camera with interference filters (red).](image-url)

We consider a dual-rotating Mueller polarimeter composed of the following elements, from source to detector (see Figure 1):

- A medium, represented by its Mueller matrix \( M \), to be analyzed;
- A medium \( M \) to be analyzed;
- A polarization state generator (PSG) comprising:
  - a linear polarizer \( P^G \) with angle \( \theta^G \);
  - a retarder \( R^G \) with controllable fast axis (azimuth) \( \alpha^G \);
- A medium \( M \) to be analyzed;
- A polarization state analyzer (PSA) comprising:
  - a retarder \( R^A \) with controllable azimuth \( \alpha^A \);
  - a linear polarizer \( P^A \) with angle \( \theta^A \);
- A CCD camera equipped with interference filters.

In dual-rotating Mueller polarimetry [11–14], both polarizers are kept fixed while several images are acquired under varying azimuthal angles of the retarders. The optical properties of the medium, represented by its Mueller matrix \( M \), can be obtained by solving a system of equations having the following form:

\[
\begin{bmatrix}
I \\
Q \\
U \\
V
\end{bmatrix}^\top \propto
\begin{bmatrix}
M \\
R^A \\
R^G
\end{bmatrix}
\begin{bmatrix}
p^A \\
p^G
\end{bmatrix}
\begin{bmatrix}
1 & 0 & 0 \\
0 & 1 & 0 \\
0 & 0 & 1
\end{bmatrix},
\]

where \([I, 0, 0, 0]^\top\) is the Stokes vector of the (unpolarized) light entering the PSG, the lhs is the Stokes vector of the (polarized) light entering the detector, with \( I \) the intensity measured by the camera, and the Mueller matrices in the rhs are given the same name as the optical element they represent.

---

1In our experiments, we used Newport 10LP-VIS-B polarizers and Newport 10BPW-532 zero-order waveplates, with a Stingray F-033B graylevel camera, Newport 10BPFF10 band-pass filters and Newport AG-PR00P piezo rotation stages to control the angles from 0° to 340° with a resolution of 0.001°.
We first describe a sequential calibration procedure where the Stokes vector \( G \) and of the first row of the PSA matrix \( A \). That is to say, the matrices \( P^A, R^A, R^G, P^G \) need to be calibrated. However, as shown in

\[
R(x; \theta_0, \delta_0) \propto \begin{bmatrix}
1 & 0 & 0 & 0 \\
0 & \cos 2\theta_0 & \sin 2\theta_0 & 0 \\
0 & -\sin 2\theta_0 & \cos 2\theta_0 & 0 \\
0 & 0 & 0 & 1
\end{bmatrix}
\]

and

\[
P(\theta; \theta_0) \propto \begin{bmatrix}
1 & \cos 2\theta & \sin 2\theta & 0 \\
\cos 2\theta & 1 & 0 & 0 \\
\sin 2\theta & 0 & 1 & 0 \\
0 & 0 & 0 & 1
\end{bmatrix}
\]

these matrices have closed-form expressions involving the angles \( \theta^G, \theta^A, \alpha^G, \) and \( \alpha^A \), which are defined w.r.t. unknown reference angles (indexed with a zero). Moreover, the Mueller matrices of the retarders involve the delays \( \delta_{0}^{G/A}, \) which also need to be calibrated as functions of the wavelength.

Inaccurate calibration has long been identified as a source of serious bias in Mueller polarimetry [5], but as mentioned earlier there is a surprising lack of literature on accurate and simple calibration techniques. The rest of this study describes two such techniques. The rest of this study describes two such techniques. The rest of this study describes two such techniques.

A. Sequential polarimeter calibration

We first describe a sequential calibration procedure where the optical elements are added to the setup and calibrated one after the other, as advocated e.g., in [5, 12]. To calibrate the PSA polarizer, the PSG polarizer is present but both retarders are removed \( (R^A = R^G = I) \). Our goal is to calibrate the orientation \( \theta^G \) of the PSA polarizer w.r.t. that of the PSG, provided that the angle of the PSG is a diagonal matrix with elements \([1, 1, 1, 1]^{T}\).

To calibrate the PSG retarder, the PSA retarder is removed \( (R^A = I) \), and the angles of both polarizers are set to zero \( (\theta^G = \theta_0^G \text{ and } \theta^A = \theta_0^A) \). The unknowns are the angle \( \delta^G \) and the delay \( \delta^A \) (which is a function of the wavelength). To estimate them, we take \( m \) series of shots under different wavelength \( \lambda_i \), \( i \in \{1, \ldots, m\} \), and for each series \( i \) we record \( n \) measurements \( I_i^j, k \in \{1, \ldots, n\} \) under varying angle \( \kappa^G, k \in \{1, \ldots, n\} \). Let us assume again homoskedastic, zero-mean Gaussian noise, and denote by \( b_i \) the proportionality constant (which is wavelength-dependent, due to the sensor response being wavelength-dependent) and by \( \delta_0^G \) the delay for the wavelength \( \lambda_i \). By expanding the first row of Eq. (1) along with Eq. (2) and Eq. (3), the maximum likelihood estimation for the set of unknown parameters \( \{\delta_0^G, \{b_i \delta_{0}^{G,i}\} \}_{i=1}^{\{1, \ldots, m\}} \) is attained by solving the following nonlinear least-squares problem using, e.g., Levenberg-Marquardt’s algorithm:

\[
\min_{\delta_{0}^{G,i}} \sum_{i=1}^{m} \sum_{k=1}^{n} \left( b_i^2 + \left( \sin^2 \left( \frac{2(k \alpha^G - \delta_{0}^{G,i})}{\lambda_0} \right) - \frac{2}{\lambda^i} \right) \right)^2.
\]

Then, from the estimated values \( \{\delta_0^G, \{b_i \delta_{0}^{G,i}\} \}_{i=1}^{\{1, \ldots, m\}} \) of the delays we can obtain the delay value for any wavelength \( \lambda \) according to Cauchy’s approximation

\[
\delta^G_0(\lambda) = \frac{\kappa^G_1}{\lambda} + \frac{\kappa^G_2}{\lambda^2}.
\]

B. Bundle-adjusted polarimeter calibration

Given the sequential nature of the previous approach, bias may be accumulated through the procedure (e.g., a wrong calibration of the PSA polarizer will bias the calibration of the PSG retarder, and that of the PSA retarder even more). Moreover, slight displacements of the optical elements between the numerous steps may be another source of bias. Therefore, an integrated calibration method for the joint estimation of all parameters (the three angles \( \theta^A, \alpha^G, \) and \( \alpha^A \), and the four parameters \( \kappa_{1/2}^{G/A} \) of the two delay functions \( \delta_{0}^{G/A} \) modeled as in Eq. (6)) would require less manual intervention, and be more accurate. We now introduce such a method, which is inspired by the classic bundle adjustment method widely used in computer vision [17].

Let us consider a series of measurements \( I_i^j \) obtained under varying wavelength \( \{\lambda_i\} \), polarizer angle \( \{\theta^A\} \), PSG azimuth \( \{\alpha^G\} \) and PSA azimuth \( \{\alpha^A\} \). We used 6 wavelengths and 8 different values for the angles taken every 22.5° between 0° and 157.5° for the azimuths \( \alpha^{G/A} \), and every 45° between 0° and 315° for the polarizer angles \( \delta_{0}^{G/A} \).

The left column in Figure 2 shows an example of results obtained with this approach, while calibrating the polarimeter shown in Figure 1.
Let us assume that Eq. (1) is satisfied up to additive, zero-mean and homoskedastic Gaussian noise, and denote by $b^i$ the unknown scale parameter for the $i$-th wavelength. The maximum likelihood estimate for the set of unknown parameters is thus attained by solving the nonlinear least-squares problem

$$\min_{b,\kappa^0} \sum_{i,j,k,l} \left( b^i I_i^j(A_i^0, k_1^A, k_2^A, \theta_0^A) M_k G_i^j(A_i^0, k_1^G, k_2^G) - I_i^j \right)^2$$

with $I^j_i$ the first row of the PSA matrix $A$ in Eq. (1) given, according to Eq. (2), Eq. (3) and Eq. (6), by

$$I^j_i(A_i^0, k_1^A, k_2^A, \theta_0^A) = \left[ \begin{array}{c} \cos^2 (\theta_i^0 - \theta_0^0) + \cos \left( \frac{\theta_i^0}{\lambda_i} - \frac{\theta_0^0}{\lambda_i} \right) \sin^2 (\theta_i^0 - \theta_0^0) \\ \sin^2 (\theta_i^0 - \theta_0^0) \left( 1 - \cos \left( \frac{\theta_i^0}{\lambda_i} + \frac{\theta_0^0}{\lambda_i} \right) \right) \sin (\theta_i^0 - \theta_0^0) \\ \cos^2 (\theta_i^0 - \theta_0^0) \left( 1 - \cos \left( \frac{\theta_i^0}{\lambda_i} + \frac{\theta_0^0}{\lambda_i} \right) \right) \sin (\theta_i^0 - \theta_0^0) \\ \cos^2 (\theta_i^0 - \theta_0^0) \sin (\frac{\theta_i^0}{\lambda_i} - \frac{\theta_0^0}{\lambda_i}) \sin (\theta_i^0 - \theta_0^0) \left( \frac{\theta_i^0}{\lambda_i} + \frac{\theta_0^0}{\lambda_i} \right) \cos (\theta_i^0 - \theta_0^0) \\ \end{array} \right]$$

and $I^j_i$ the Stokes vector exiting the PSG given, according to Eq. (2), Eq. (3) and Eq. (6), by

$$I^j_i(A_i^0, k_1^G, k_2^G) = \left[ \begin{array}{c} \cos \left( \frac{\theta_i^0}{\lambda_i} + \frac{\theta_0^0}{\lambda_i} \right) \sin^2 (\theta_i^0 - \theta_0^0) + \cos^2 (\theta_i^0 - \theta_0^0) \\ (1 - \cos \left( \frac{\theta_i^0}{\lambda_i} + \frac{\theta_0^0}{\lambda_i} \right)) \cos (\theta_i^0 - \theta_0^0) \sin (\theta_i^0 - \theta_0^0) \\ - \sin \left( \frac{\theta_i^0}{\lambda_i} + \frac{\theta_0^0}{\lambda_i} \right) \sin (\theta_i^0 - \theta_0^0) \end{array} \right].$$

The angles estimated with this integrated approach differ by less than $2^\circ$ from those obtained with the sequential approach, thus we do not reproduce any new calibration result. It is the computation of real-world Mueller matrix measurements which will highlight the significance of this slight difference. Still, let us already remark that in the sequential procedure, we used a total of $3 \times 3400 = 10200$ observations per wavelength. In contrast, we used 20 times less (512 per wavelength) observations for the bundle-adjusted method: if the latter is to provide similar results with so much fewer observations then it can be considered as substantially better in terms of simplicity.

### C. Polarimetric Imaging

To measure real-world Mueller matrices, the polarizers are aligned ($\theta^A = \theta^0$, $\theta^G = \theta_0^G$) and the two retarders are controlled through their azimuths $\alpha^G := \alpha^G - \theta_0^G$ and $\alpha^A := \alpha^A - \theta_0^A$. The first row in Eq. (1) then turns into the following linear equation in the 16 unknown coefficients of matrix $M$:

$$I(\alpha^A, \alpha^G) = \left[ \begin{array}{c} 1 - (1 - \cos \theta_0^G) \sin^2 2\alpha^A \\ (1 - \cos \theta_0^G) \cos 2\alpha^A \sin 2\alpha^A \end{array} \right].$$

We acquire $m$ series of intensity measurements under varying PSA retarder angle $\alpha^A$. In each series, we acquire $n$ measurements under varying PSG retarder angle $\alpha^G$. The resulting $mn$ observations then allow the system of $mn$ equations such as Eq. (10) to be solved in the least-squares sense.

---

Our piezo rotating stages being limited to a speed of 1.5 $\text{deg/s}$, in our experiments it takes around 1.5 hrs to acquire the 512 measurements used to calibrate the polarimeter at one particular wavelength, and around 10 min to acquire the 64 ones used for polarimetric imaging. These numbers might be significantly reduced by using faster rotating stages.

We used $m = n = 8$ angles equally spaced between $0^\circ$ and $157.5^\circ$. This yields conditioning numbers of 3.79 and 3.99 for the 64 $\times$ 4 matrices $A$ and $G$ in Eq. (10). These values are exactly the same as those associated with the theoretically optimal [6] set of 64 angles obtained with synchronous variations of both azimuths at a 1:3 speed ratio.
We first calibrated the polarimeter in transmission mode and then estimated the Mueller matrix\(^9\) of the air at 540 nm (the expected result is the matrix \(M^{\text{air}}\) equal to identity). Then we calibrated it again in reflection mode and estimated the Mueller matrix of a mirror at 540 nm (the expected result is a diagonal matrix \(M^{\text{mirr}}\) with non-zero elements \([1, 1, -1, -1]^\top\)). The results shown in Table 1 show that the bundle-adjusted calibration method significantly reduces errors. The spatial uniformity of the error distribution further suggests that the remaining errors are mostly due to the accuracy of the detector.

Figure 3 illustrates the ability of the discussed polarimeter, calibrated in reflection mode, to reconstruct spatially-varying Mueller matrix fields. In this experiment the scene contains three objects whose material can hardly be discriminated from the graylevel image (see the top-left image), but visualization of the Mueller matrix coefficients (for instance, \(M_{22}\) and \(M_{43}\)) makes this task straightforward. This shows the potential of the proposed simplified calibration procedure for Mueller polarimeters in material classification.
